The MCU system clock frequency (IMB3 system clock –  $f_{\text{SYSCLK}}$ ) is the basis of the QADC64E timing. QCLK is generated by a software selectable prescaler that divides  $f_{\text{SYSCLK}}$  thus allowing the A/D conversion time to be maximized across  $f_{\text{SYSCLK}}$ . The software establishes the frequency of QCLK waveform by setting the PRESCALER field in the QACR0 register.

When the value of PRESCALER > 0 the resulting frequency of QCLK is calculated using the following formula:

$$f_{\text{QCLK}} = f_{\text{SYSCLK}} / (\text{PRESCALER} + 1)$$

The QADC64E requires that  $f_{\text{SYSCLK}}$  be at least twice  $f_{\text{QCLK}}$ . Therefore if the value in the PRESCALER field is set to Zero, the resulting QCLK frequency is calculated to be:

$$f_{\text{QCLK}} = f_{\text{SYSCLK}} / 2$$

**Table 14-22. QADC64E Clock Programmability**

| Control Register 0 Information |           |           | Input Sample Time (IST) =0 |                      |
|--------------------------------|-----------|-----------|----------------------------|----------------------|
| Example Number                 | Frequency | PRESCALER | QCLK (MHz)                 | Conversion Time (μs) |
| 1                              | 20 MHz    | 0x09      | 2.0                        | 7.0                  |
| 2                              | 40 MHz    | 0x13      | 2.0                        | 7.0                  |
| 3                              | 56 MHz    | 0x1B      | 2.0                        | 7.0                  |

### 14.4.6 Periodic/Interval Timer

The on-chip periodic/interval timer can be used to generate trigger events at a programmable interval, initiating execution of queue 1 and/or queue 2. The periodic/interval timer stays reset under the following conditions:

- Both queue 1 and queue 2 are programmed to any mode which does not use the periodic/interval timer
- IMB3 system reset or the master reset is asserted
- Stop mode is selected
- Freeze mode is selected

#### NOTE

Interval timer single-scan mode does not use the periodic/interval timer until the single-scan enable bit is set.

The following two conditions will cause a pulsed reset of the periodic/interval timer during use:

- A queue 1 operating mode change to a mode which uses the periodic/interval timer, even if queue 2 is already using the timer
- A queue 2 operating mode change to a mode which uses the periodic/interval timer, provided queue 1 is not in a mode which uses the periodic/interval timer
- Roll over of the timer

During the low power stop mode, the periodic timer is held in reset. Since low power stop mode causes QACR1 and QACR2 to be reset to zero, a valid periodic or interval timer mode must be written after stop mode is exited to release the timer from reset.

When the IMB3 internal FREEZE line is asserted and a periodic or interval timer mode is selected, the timer counter is reset after the conversion in progress completes. When the periodic or interval timer mode has been enabled (the timer is counting), but a trigger event has not been issued, the freeze mode takes effect immediately, and the timer is held in reset. When the internal FREEZE line is negated, the timer counter starts counting from the beginning. Refer to [Section 14.4.7, “Configuration and Control Using the IMB3 Interface”](#) for more information.

## 14.4.7 Configuration and Control Using the IMB3 Interface

The QADC64E module communicates with other microcontroller modules via the IMB3. The QADC64E bus interface unit (BIU) coordinates IMB3 activity with internal QADC64E bus activity. This section describes the operation of the BIU, IMB3 read/write accesses to QADC64E memory locations, module configuration, and general-purpose I/O operation.

### 14.4.7.1 QADC64E Bus Interface Unit

The BIU is designed to act as a slave device on the IMB3. The BIU has the following functions: to respond with the appropriate bus cycle termination, and to supply IMB3 interface timing to all internal module signals.

BIU components consist of

- IMB3 buffers
- Address match and module select logic
- The BIU state machine
- Clock prescaler logic
- Data bus routing logic
- Interface to the internal module data bus

#### NOTE

Normal accesses from the IMB3 to the QADC64E require two clocks. However, if the CPU tries to access table locations while the QADC64E is accessing them, the QADC64E produces IMB3 wait states. From one to four IMB3 wait states may be inserted by the QADC64E in the process of reading and writing.

### 14.4.7.2 QADC64E Bus Accessing

The QADC64E supports 8-bit, 16-bit, and 32-bit data transfers, at even and odd addresses. Coherency of results read (ensuring that all results read were taken consecutively in one scan) is not guaranteed. For example, if a read of two consecutive 16-bit locations in a result area is made, the QADC64E could change one 16-bit location in the result area between the bus cycles. There is no holding register for the second 16-bit location. All read and write accesses that require more than one 16-bit access to complete occur as two or more independent bus cycles. Depending on bus master protocol, these accesses could include misaligned and 32-bit accesses.

Figure 14-24 shows the three bus cycles which are implemented by the QADC64E. The following paragraphs describe how the three types of accesses are used, including misaligned 16-bit and 32-bit accesses.

**Figure 14-24. Bus Cycle Accesses**

Byte access to an even address of a QADC64E location is shown in the top illustration of [Figure 14-24](#). In the case of write cycles, byte 1 of the register is not disturbed. In the case of a read cycle, the QADC64E provides both byte 0 and byte 1.

Byte access to an odd address of a QADC64E location is shown in the center illustration of [Figure 14-24](#). In the case of write cycles, byte 0 of the register is not disturbed. In the case of read cycles, the QADC64E provides both byte 0 and byte 1.

16-bit accesses to an even address read or write byte 0 and byte 1 as shown in the lowest illustration of [Figure 14-24](#). The full 16 bits of data is written to and read from the QADC64E location with each access.

16-bit accesses to an odd address require two bus cycles; one byte of two different 16-bit QADC64E locations is accessed. The first bus cycle is treated by the QADC64E as an 8-bit read or write of an odd address. The second cycle is an 8-bit read or write of an even address. The QADC64E address space is organized into 16-bit even address locations, so a 16-bit read or write of an odd address obtains or provides the lower half of one QADC64E location, and the upper half of the following QADC64E location.

32-bit accesses to an even address require two bus cycles to complete the access, and two full 16-bit QADC64E locations are accessed. The first bus cycle reads or writes the addressed 16-bit QADC64E location and the second cycle reads or writes the following 16-bit location.

32-bit accesses to an odd address require three bus cycles. Portions of three different QADC64E locations are accessed. The first bus cycle is treated by the QADC64E as an 8-bit access of an odd address, the second cycle is a 16-bit aligned access, and the third cycle is an 8-bit access of an even address. The QADC64E address space is organized into 16-bit even address locations, so a 32-bit read or write of an odd address provides the lower half of one QADC64E location, the full 16-bit content of the following QADC64E location, and the upper half of the third QADC64E location.

## 14.5 Trigger and Queue Interaction Examples

This section contains examples describing queue priority and conversion timing schemes.

### 14.5.1 Queue Priority Schemes

Since there are two conversion command queues and only one A/D converter, there is a priority scheme to determine which conversion is to occur. Each queue has a variety of trigger events that are intended to initiate conversions, and they can occur asynchronously in relation to each other and other conversions in progress. For example, a queue can be idle awaiting a trigger event, a trigger event can have occurred but the first conversion has not started, a conversion can be in progress, a pause condition can exist awaiting another trigger event to continue the queue, and so on.

The following paragraphs and figures outline the prioritizing criteria used to determine which conversion occurs in each overlap situation.

#### NOTE

The situations in [Figure 14-25](#) through [Figure 14-43](#) are labeled S1 through S19. In each diagram, time is shown increasing from left to right. The execution of queue 1 and queue 2 (Q1 and Q2) is shown as a string of rectangles representing the execution time of each CCW in the queue. In most of the situations, there are four CCWs (labeled C1 to C4) in both queue 1 and queue 2. In some of the situations, CCW C2 is presumed to have the pause bit set, to show the similarities of pause and end-of-queue as terminations of queue execution.

Trigger events are described in [Table 14-23](#).

**Table 14-23. Trigger Events**

| Trigger | Events                                                                                                                                                                            |
|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| T1      | Events that trigger queue 1 execution (external trigger, software initiated single-scan enable bit, or completion of the previous continuous loop)                                |
| T2      | Events that trigger queue 2 execution (external trigger, software initiated single-scan enable bit, timer period/interval expired, or completion of the previous continuous loop) |

When a trigger event causes a CCW execution in progress to be aborted, the aborted conversion is shown as a ragged end of a shortened CCW rectangle.

The situation diagrams also show when key status bits are set. [Table 14-24](#) describes the status bits.

**Table 14-24. Status Bits**

| Bit                         | Function                                                                                            |
|-----------------------------|-----------------------------------------------------------------------------------------------------|
| CF Flag                     | Set when the end of the queue is reached                                                            |
| PF Flag                     | Set when a queue completes execution up through a pause bit                                         |
| Trigger Overrun Error (TOR) | Set when a new trigger event occurs before the queue is finished serving the previous trigger event |

Below the queue execution flows are three sets of blocks that show the status information that is made available to the software. The first two rows of status blocks show the condition of each queue as:

- Idle
- Active
- Pause
- Suspended (queue 2 only)
- Trigger pending

The third row of status blocks shows the 4-bit QS status register field that encodes the condition of the two queues. Two transition status cases, QS = 0011 and QS = 0111, are not shown because they exist only very briefly between stable status conditions.

The first three examples in [Figure 14-25](#) through [Figure 14-27](#) (S1, S2, and S3) show what happens when a new trigger event is recognized before the queue has completed servicing the previous trigger event on the same queue.

In situation S1 ([Figure 14-25](#)), one trigger event is being recognized on each queue while that queue is still working on the previously recognized trigger event. The trigger overrun error status bit is set, and otherwise, the premature trigger event is ignored. A trigger event which occurs before the servicing of the previous trigger event is through does not disturb the queue execution in progress.

**Figure 14-25. CCW Priority Situation 1**

In situation S2 (Figure 14-25), more than one trigger event is recognized before servicing of a previous trigger event is complete, the trigger overrun bit is again set, but otherwise, the additional trigger events are ignored. After the queue is complete, the first newly detected trigger event causes queue execution to begin again. When the trigger event rate is high, a new trigger event can be seen very soon after completion of the previous queue, leaving software little time to retrieve the previous results. Also, when trigger events are occurring at a high rate for queue 1, the lower priority queue 2 channels may not get serviced at all.

**Figure 14-26. CCW Priority Situation 2**

Situation S3 (Figure 14-26) shows that when the pause feature is in use, the trigger overrun error status bit is set the same way, and that queue execution continues unchanged.

Figure 14-27. CCW Priority Situation 3

The next two situations consider trigger events that occur for the lower priority queue 2, while queue 1 is actively being serviced.

Situation S4 (Figure 14-28) shows that a queue 2 trigger event that is recognized while queue 1 is active is saved, and as soon as queue 1 is finished, queue 2 servicing begins.

Figure 14-28. CCW Priority Situation 4

Situation S5 (Figure 14-29) shows that when multiple queue 2 trigger events are detected while queue 1 is busy, the trigger overrun error bit is set, but queue 1 execution is not disturbed. Situation S5 also shows that the effect of queue 2 trigger events during queue 1 execution is the same when the pause feature is in use in either queue.

**Figure 14-29. CCW Priority Situation 5**

The remaining situations, S6 through S11, show the impact of a queue 1 trigger event occurring during queue 2 execution. Queue 1 is higher in priority the conversion taking place in queue 2 is aborted, so that there is not a variable latency time in responding to queue 1 trigger events.

In situation S6 (Figure 14-30), the conversion initiated by the second CCW in queue 2 is aborted just before the conversion is complete, so that queue 1 execution can begin. Queue 2 is considered suspended. After queue 1 is finished, queue 2 starts over with the first CCW, when the RES (resume) control bit is set to 0. Situation S7 (Figure 14-31) shows that when pause operation is not in use with queue 2, queue 2 suspension works the same way.

**Figure 14-30. CCW Priority Situation 6**

Figure 14-31. CCW Priority Situation 7

Situations S8 and S9 (Figure 14-32 and Figure 14-33) repeat the same two situations with the resume bit set to a one. When the RES bit is set, following suspension, queue 2 resumes execution with the aborted CCW, not the first CCW in the queue.

Figure 14-32. CCW Priority Situation 8

Figure 14-33. CCW Priority Situation 9

Situations S10 and S11 (Figure 14-34 and Figure 14-35) show that when an additional trigger event is detected for queue 2 while the queue is suspended, the trigger overrun error bit is set, the same as if queue 2 were being executed when a new trigger event occurs. Trigger overrun on queue 2 thus permits the software to know that queue 1 is taking up so much QADC64E time that queue 2 trigger events are being lost.

Figure 14-34. CCW Priority Situation 10

Figure 14-35. CCW Priority Situation 11

The above situations cover normal overlap conditions that arise with asynchronous trigger events on the two queues. An additional conflict to consider is that the freeze condition can arise while the QADC64E is actively executing CCWs. The conventional use for the freeze mode is for software/hardware debugging. When the CPU background debug mode is enabled and a breakpoint occurs, the freeze signal is issued, which can cause peripheral modules to stop operation. When freeze is detected, the QADC64E completes the conversion in progress, unlike queue 1 suspending queue 2. After the freeze condition is removed, the QADC64E continues queue execution with the next CCW in sequence.

Trigger events that occur during freeze are not captured. When a trigger event is pending for queue 2 before freeze begins, that trigger event is remembered when the freeze is passed. Similarly, when freeze occurs while queue 2 is suspended, after freeze, queue 2 resumes execution as soon as queue 1 is finished.

Situations 12 through 19 (Figure 14-36 to Figure 14-43) show examples of all of the freeze situations.

## 14.5.2 Conversion Timing Schemes

This section contains some conversion timing examples. Example 1 below shows the timing for basic conversions where the following is assumed:

- Q1 begins with CCW0 and ends with CCW3
- CCW0 has pause bit set
- CCW1 does not have pause bit set
- External trigger rise-edge for Q1
- CCW4 = BQ2 and Q2 is disabled

- Q1 RES shows relative result register updates

**Figure 14-44. External Trigger Mode (Positive Edge) Timing with Pause**

Recall  $QS = 0 \Rightarrow$  Queues disabled;  $QS = 8 \Rightarrow$  Q1 active, Q2 disabled;  $QS = 4 \Rightarrow$  Q1 paused, Q2 disabled.

A time separator was provided between the triggers and end of conversion (EOC). The relationship to QCLK displayed is not guaranteed.

CWPQ1 or CWPQ2 typically lag CWP and only match CWP when the associated queue is inactive. Another way to view CWPQ1(2) is that these registers update when EOC triggers the result register to be written.

When the pause bit is set (CCW0), please note that CWP does not increment until triggered. When the pause is not set (CCW1), the CWP increments with EOC.

The conversion results Q1 RES(x) show the result associated with CCW(x). So that R0 represents the result associated with CCW0.

Example 2 below shows the timing for conversions in gated mode single-scan with the same assumptions as example 1 except:

- No pause bits set in any CCW
- External trigger gated single-scan mode for Q1
- Single-scan bit is set

When the gate closes and opens again the conversions start with the first CCW in Q1.

When the gate closes the active conversion completes before the queue goes idle.

When Q1 completes both the CF1 bit sets and the SSE bit clears.

**Figure 14-45. Gated Mode, Single-Scan Timing**

Example 3 below shows the timing for conversions in gated continuous-scan mode with the same assumptions in the amended definition for the PF bit in this mode to reflect the condition that a gate closing occurred before the queue completed is a proposal under consideration at this time as example 2.

### NOTE

At the end of Q1, the completion flag CF1 sets and the queue restarts. Also, note that if the queue starts a second time and completes, the trigger overrun flag TOR1 sets.

Figure 14-46. Gated Mode, Continuous Scan Timing

## 14.6 QADC64E Integration Requirements

The QADC64E requires accurate, noise-free input signals for proper operation. This section discusses the design of external circuitry to maximize QADC64E performance.

The QADC64E uses the external signals shown in [Figure 14-1](#). There are 16 channel signals that can also be used as general-purpose digital input/output signals. With external multiplexing MPC561/MPC563 can support 41 analog inputs. In addition, there are three analog reference signals and two analog submodule power signals, shared by each QADC64E module.

### 14.6.1 Port Digital Input/Output Signals

The sixteen port signals can be used as analog inputs, or as a bidirectional 16-bit digital input/output port.

Port A signals are referred to as PQA[7:0] when used as a bidirectional 8-bit digital input/output port. These eight signals may be used for general-purpose digital input signals or push-pull digital output signals. Port B signals are referred to as PQB[7:0] and operate the same as Port A.

Port A and B signals are connected to a digital input synchronizer during reads and may be used as general purpose digital inputs when the applied voltages meet high voltage input ( $V_{IH}$ ) and low voltage input ( $V_{IL}$ ) requirements. Refer to [Appendix F, “Electrical Characteristics,”](#) for more information on voltage requirements.

Each port A or B signal is configured as an input or output by programming the port data direction register (DDRQA or DDRQB). The digital input signal states are read by the software in the upper half of the port data register when the port data direction register specifies that the signals are inputs. The digital data in the port data register is driven onto the port A or B signals when the corresponding bit in the port data direction register specifies output. Refer to [Appendix B, “Internal Memory Map”](#) for more information. Since the outputs are configured as push-pull drivers, external pull-up provisions are not necessary when the output is used to drive another integrated circuit.

## 14.6.2 External Trigger Input Signals

The QADC64E uses two external trigger signals (ETRIG[2:1]). Each of the two input external trigger signals is associated with one of the scan queues, queue 1 or queue 2. The assignment of ETRIG[2:1] to a queue is made in the QACR0 register by the TRG bit. When TRG=0, ETRIG1 triggers queue 1 and ETRIG2 triggers queue 2. When TRG=1, ETRIG1 triggers queue 2 and ETRIG2 triggers queue 1.

## 14.6.3 Analog Power Signals

$V_{DDA}$  and  $V_{SSA}$  signals supply power to the analog subsystems of the QADC64E module. Dedicated power is required to isolate the sensitive analog circuitry from the normal levels of noise present on the digital power supply. Refer to [Appendix F, “Electrical Characteristics,”](#) for more information.

The analog supply signals ( $V_{DDA}$  and  $V_{SSA}$ ) define the limits of the analog reference voltages ( $V_{RH}$  and  $V_{RL}$ ) and of the analog multiplexer inputs. [Figure 14-47](#) is a diagram of the analog input circuitry.

**Figure 14-47. Equivalent Analog Input Circuitry**

Since the sample amplifier is powered by  $V_{DDA}$  and  $V_{SSA}$ , it can accurately transfer input signal levels up to but not exceeding  $V_{DDA}$  and down to but not below  $V_{SSA}$ . If the input signal is outside of this range, the output from the sample amplifier is clipped.

In addition,  $V_{RH}$  and  $V_{RL}$  must be within the range defined by  $V_{DDA}$  and  $V_{SSA}$ . As long as  $V_{RH}$  is less than or equal to  $V_{DDA}$  and  $V_{RL}$  is greater than or equal to  $V_{SSA}$  and the sample amplifier has accurately transferred the input signal, resolution is ratiometric within the limits defined by  $V_{RL}$  and  $V_{RH}$ . If  $V_{RH}$  is greater than  $V_{DDA}$ , the sample amplifier can never transfer a full-scale value. If  $V_{RL}$  is less than  $V_{SSA}$ , the sample amplifier can never transfer a zero value.

Figure 14-48 shows the results of reference voltages outside the range defined by  $V_{DDA}$  and  $V_{SSA}$ . At the top of the input signal range,  $V_{DDA}$  is 10 mV lower than  $V_{RH}$ . This results in a maximum obtainable 10-bit conversion value of 0x3FE. At the bottom of the signal range,  $V_{SSA}$  is 15 mV higher than  $V_{RL}$ , resulting in a minimum obtainable 10-bit conversion value of three.

Figure 14-48. Errors Resulting from Clipping

### 14.6.3.1 Analog Supply Filtering and Grounding

Two important factors influencing performance in analog integrated circuits are supply filtering and grounding. Generally, digital circuits use bypass capacitors on every  $V_{DD}/V_{SS}$  signal pair. This applies to analog sub-modules also. The distribution of power and ground is equally important.

Analog supplies should be isolated from digital supplies as much as possible. This necessity stems from the higher performance requirements often associated with analog circuits. Therefore, deriving an analog supply from a local digital supply is not recommended. However, if for economic reasons digital and analog power are derived from a common regulator, filtering of the analog power is recommended in addition to the bypassing of the supplies already mentioned.

#### NOTE

An RC low pass filter could be used to isolate the digital and analog supplies when generated by a common regulator. If multiple high precision analog circuits are locally employed (i.e., two A/D converters), the analog supplies should be isolated from each other as sharing supplies introduces the potential for interference between analog circuits.

Grounding is the most important factor influencing analog circuit performance in mixed signal systems (or in stand-alone analog systems). Close attention must be paid not to introduce additional sources of noise into the analog circuitry. Common sources of noise include ground loops, inductive coupling, and combining digital and analog grounds together inappropriately.

The problem of how and when to combine digital and analog grounds arises from the large transients which the digital ground must handle. If the digital ground is not able to handle the large transients, the current from the large transients can return to ground through the analog ground. It is the excess current overflowing into the analog ground which causes performance degradation by developing a differential voltage between the true analog ground and the microcontroller's ground signal. The end result is that the ground observed by the analog circuit is no longer true ground and often ends in skewed results.

Two similar approaches designed to improve or eliminate the problems associated with grounding excess transient currents involve star-point ground systems. One approach is to star-point the different grounds at the power supply origin, thus keeping the ground isolated. Refer to [Figure 14-49](#).

**Figure 14-49. Star-Ground at the Point of Power Supply Origin**

Another approach is to star-point the different grounds near the analog ground signal on the microcontroller by using small traces for connecting the non-analog grounds to the analog ground. The small traces are meant only to accommodate DC differences, not AC transients.

### NOTE

This star-point scheme still requires adequate grounding for digital and analog subsystems in addition to the star-point ground.

Other suggestions for PCB layout in which the QADC64E is employed include:

- Analog ground must be low impedance to all analog ground points in the circuit.
- Bypass capacitors should be as close to the power signals as possible.
- The analog ground should be isolated from the digital ground. This can be done by cutting a separate ground plane for the analog ground.
- Non-minimum traces should be utilized for connecting bypass capacitors and filters to their corresponding ground/power points.
- Distance for trace runs should be minimized where possible.

## 14.6.4 Analog Reference Signals

$V_{RH}$  and  $V_{RL}$  are the dedicated input signals for the high and low reference voltages. Separating the reference inputs from the power supply signals allows for additional external filtering, which increases reference voltage precision and stability, and subsequently contributes to a higher degree of conversion accuracy.

The AltRef signal may be selected through the CCW as the high reference for a conversion. This allows for the ability to “zoom” in on a portion of the convertible range with the full 10 bits. Refer to [Table 14-19](#).

No A/D converter can be more accurate than its analog reference. Any noise in the reference can result in at least that much error in a conversion. The reference for the QADC64E, supplied by signals  $V_{RH}$ , AltRef, and  $V_{RL}$ , should be low-pass filtered from its source to obtain a noise-free, clean signal. In many cases, simple capacitive bypassing may suffice. In extreme cases, inductors or ferrite beads may be necessary if noise or RF energy is present. Series resistance is not advisable since there is an effective DC current requirement from the reference voltage by the internal resistor string in the RC DAC array. External resistance may introduce error in this architecture under certain conditions. Any series devices in the filter network should contain a minimum amount of DC resistance.

### 14.6.5 Analog Input Signals

Analog inputs should have low AC impedance at the signals. Low AC impedance can be realized by placing a capacitor with good high frequency characteristics at the input signal of the part. Ideally, that capacitor should be as large as possible (within the practical range of capacitors that still have good high frequency characteristics). This capacitor has two effects:

- It helps attenuate any noise that may exist on the input.
- It sources charge during the sample period when the analog signal source is a high-impedance source.

Series resistance can be used with the capacitor on an input signal to implement a simple RC filter. The maximum level of filtering at the input signals is application dependent and is based on the bandpass characteristics required to accurately track the dynamic characteristics of an input. Simple RC filtering at the signal may be limited by the source impedance of the transducer or circuit supplying the analog signal to be measured. Refer to [Section 14.6.5.3, “Error Resulting from Leakage”](#) for more information. In some cases, the size of the capacitor at the signal may be very small.

[Figure 14-50](#) is a simplified model of an input channel. Refer to this model in the following discussion of the interaction between the external circuitry and the circuitry inside the QADC64E.

$V_{SRC}$  = Source Voltage  
 $R_{SRC}$  = Source Impedance  
 $R_F$  = Filter Impedance  
 $C_F$  = Filter Capacitor  
 $C_P$  = Internal Parasitic Capacitance  
 $C_{SAMP}$  = Sample Capacitor  
 $V_I$  = Internal Voltage Source During Sample and Hold

QADC64E Sample AMP Model

**Figure 14-50. Electrical Model of an A/D Input Signal**

In [Figure 14-50](#),  $R_F$ ,  $R_{SRC}$  and  $C_F$  comprise the external filter circuit.  $C_P$  is the internal parasitic capacitor.  $C_{SAMP}$  is the capacitor array used to sample and hold the input voltage.  $V_I$  is an internal voltage source used to provide charge to  $C_{SAMP}$  during sample phase.

The following paragraphs provide a simplified description of the interaction between the QADC64E and the external circuitry. This circuitry is assumed to be a simple RC low-pass filter passing a signal from a source to the QADC64E input signal. The following simplifying assumptions are made:

- The external capacitor is perfect (no leakage, no significant dielectric absorption characteristics, etc.)
- All parasitic capacitance associated with the input signal is included in the value of the external capacitor
- Inductance is ignored
- The “on” resistance of the internal switches is  $0\ \Omega$  and the “off” resistance is infinite

### 14.6.5.1 Analog Input Considerations

The source impedance of the analog signal to be measured and any intermediate filtering should be considered whether external multiplexing is used or not. [Figure 14-51](#) shows the connection of eight typical analog signal sources to one QADC64E analog input signal through a separate multiplexer chip. Also, an example of an analog signal source connected directly to a QADC64E analog input channel is displayed.

Figure 14-51. External Multiplexing of Analog Signal Sources

### 14.6.5.2 Settling Time for the External Circuit

The values for  $R_{SRC}$ ,  $R_F$  and  $C_F$  in the external circuitry determine the length of time required to charge  $C_F$  to the source voltage level ( $V_{SRC}$ ). At time  $t = 0$ ,  $V_{SRC}$  changes in [Figure 14-50](#) while S1 is open, disconnecting the internal circuitry from the external circuitry. Assume that the initial voltage across  $C_F$  is zero. As  $C_F$  charges, the voltage across it is determined by the following equation, where  $t$  is the total charge time:

As  $t$  approaches infinity,  $V_{CF}$  will equal  $V_{SRC}$ . (This assumes no internal leakage.) With 10-bit resolution, 1/2 of a count is equal to 1/2048 full-scale value. Assuming worst case ( $V_{SRC}$  = full scale), [Table 14-25](#) shows the required time for  $C_F$  to charge to within 1/2 of a count of the actual source voltage during 10-bit conversions. [Table 14-25](#) is based on the RC network in [Figure 14-50](#).

#### NOTE

The following times are completely independent of the A/D converter architecture (assuming the QADC64E is not affecting the charging).

**Table 14-25. External Circuit Settling Time to 1/2 LSB (10-Bit Conversions)**

| Filter Capacitor (CF) | Source Resistance ( $R_F + R_{SRC}$ ) |              |               |                |
|-----------------------|---------------------------------------|--------------|---------------|----------------|
|                       | 100 $\Omega$                          | 1 k $\Omega$ | 10 k $\Omega$ | 100 k $\Omega$ |
| 1 $\mu$ F             | 760 $\mu$ s                           | 7.6 ms       | 76 ms         | 760 ms         |
| .1 $\mu$ F            | 76 $\mu$ s                            | 760 $\mu$ s  | 7.6 ms        | 76 ms          |
| .01 $\mu$ F           | 7.6 $\mu$ s                           | 76 $\mu$ s   | 760 $\mu$ s   | 7.6 ms         |
| .001 $\mu$ F          | 760 ns                                | 7.6 $\mu$ s  | 76 $\mu$ s    | 760 $\mu$ s    |
| 100 pF                | 76 ns                                 | 760 ns       | 7.6 $\mu$ s   | 76 $\mu$ s     |

The external circuit described in [Table 14-25](#) is a low-pass filter. A user interested in measuring an AC component of the external signal must take the characteristics of this filter into account.

### 14.6.5.3 Error Resulting from Leakage

A series resistor limits the current to a signal, therefore input leakage acting through a large source impedance can degrade A/D accuracy. The maximum input leakage current is specified in [Appendix F, “Electrical Characteristics.”](#) Input leakage is greater at higher operating temperatures. In the temperature range from 125° C to 50° C, the leakage current is halved for every 8 – 12° C reduction in temperature.

Assuming  $V_{RH} - V_{RL} = 5.12$  V, one count (assuming 10-bit resolution) corresponds to 5 mV of input voltage. A typical input leakage of 200 nA acting through 10 k $\Omega$  of external series resistance results in an error of 0.4 count (2.0 mV). If the source impedance is 100 k $\Omega$  and a typical leakage of 100 nA is present, an error of two counts (10 mV) is introduced.

In addition to internal junction leakage, external leakage (e.g., if external clamping diodes are used) and charge sharing effects with internal capacitors also contribute to the total leakage current. [Table 14-26](#) illustrates the effect of different levels of total leakage on accuracy for different values of source impedance. The error is listed in terms of 10-bit counts.

## WARNING

Leakage from the part below 200 nA is obtainable only within a limited temperature range.

**Table 14-26. Error Resulting From Input Leakage (IOFF)**

| Source Impedance | Leakage Value (10-bit Conversions) |            |            |            |
|------------------|------------------------------------|------------|------------|------------|
|                  | 100 nA                             | 200 nA     | 500 nA     | 1000 nA    |
| 1 k $\Omega$     | —                                  | —          | 0.1 counts | 0.2 counts |
| 10 k $\Omega$    | 0.2 counts                         | 0.4 counts | 1 counts   | 2 counts   |
| 100 k $\Omega$   | 2 counts                           | 4 count    | 10 counts  | 20 counts  |

### 14.6.5.4 Accommodating Positive/Negative Stress Conditions

Positive or negative stress refers to conditions which exceed nominally defined operating limits. Examples include applying a voltage exceeding the normal limit on an input (for example, voltages outside of the suggested supply/reference ranges) or causing currents into or out of the signal which exceed normal limits. QADC64E specific considerations are voltages greater than  $V_{DDA}$ ,  $V_{RH}$  or less than  $V_{SSA}$  applied to an analog input which cause excessive currents into or out of the input. Refer to [Appendix F, “Electrical Characteristics,”](#) to for more information on exact magnitudes.

Either stress condition can potentially disrupt conversion results on neighboring inputs. Parasitic devices, associated with CMOS processes, can cause an immediate disruptive influence on neighboring signals. Common examples of parasitic devices are diodes to substrate and bipolar devices with the base terminal tied to substrate ( $V_{SSI}/V_{SSA}$  ground). Under stress conditions, current injected on an adjacent signal can cause errors on the selected channel by developing a voltage drop across the selected channel’s impedances.

[Figure 14-52](#) shows an active parasitic bipolar NPN transistor when an input signal is subjected to negative stress conditions. [Figure 14-53](#) shows positive stress conditions can activate a similar PNP transistor.

**Figure 14-52. Input Signal Subjected to Negative Stress**

QADC64E PAR

**Figure 14-53. Input Signal Subjected to Positive Stress**

The current into the signal ( $I_{INJN}$  or  $I_{INJP}$ ) under negative or positive stress is determined by the following equations:

$$I_{INJN} = \frac{-(V_{STRESS} - V_{BE})}{R_{STRESS}} \quad \text{Eqn. 14-1}$$

$$I_{INJP} = \frac{V_{STRESS} - V_{EB} - V_{DDA}}{R_{STRESS}} \quad \text{Eqn. 14-2}$$

where:

$V_{STRESS}$  = Adjustable voltage source

$V_{EB}$  = Parasitic PNP emitter/base voltage

(refer to  $V_{NEGCLAMP}$  in [Appendix F, “Electrical Characteristics”](#))

$V_{BE}$  = Parasitic NPN base/emitter voltage

(refer to  $V_{NEGCLAMP}$  in [Appendix F, “Electrical Characteristics”](#))

$R_{STRESS}$  = Source impedance

(10-k $\Omega$  resistor in [Figure 14-52](#) and [Figure 14-53](#) on stressed channel)

$R_{SELECTED}$  = Source impedance on channel selected for conversion

The current into ( $I_{IN}$ ) the neighboring signal is determined by the  $K_N$  (current coupling ratio) of the parasitic bipolar transistor ( $K_N \ll 1$ ). The  $I_{IN}$  can be expressed by the following equation:

$$I_{IN} = -K_N * I_{INJ}$$

where  $I_{INJ}$  is either  $I_{INJN}$  or  $I_{INJP}$

A method for minimizing the impact of stress conditions on the QADC64E is to strategically allocate QADC64E inputs so that the lower accuracy inputs are adjacent to the inputs most likely to see stress conditions.

Also, suitable source impedances should be selected to meet design goals and minimize the effect of stress conditions.

## Chapter 15

# Queued Serial Multi-Channel Module

The MPC561/MPC563 contains one queued serial multi-channel module (QSMCM). The QSMCM provides three serial communication interfaces: the queued serial peripheral interface (QSPI) and two serial communications interfaces (SCI/UART). These submodules communicate with the CPU via a common slave bus interface unit (SBIU).

The QSPI is a full-duplex, synchronous serial interface for communicating with peripherals and other MCUs. It is enhanced from the original SPI in the QSMCM (queued serial module) to include a total of 160 bytes of queue RAM to accommodate more receive, transmit, and control information.

The duplicate, independent SCIs are full-duplex universal asynchronous receiver transmitter (UART) serial interface. The original QSM SCI is enhanced by the addition of an SCI, a common external baud clock source, receive and transmit buffers on one SCI. The SCIs are fully compatible with the SCI systems found on other Freescale MCUs. The dual, independent SCI, DSCI, submodule is used to communicate with external devices and other MCUs via an asynchronous serial bus. The DSCI has all of the capabilities of previous SCI systems as well as several significant new features. The following paragraphs describe the features, pins, programming model (memory map), registers, and the transmit and receive operations of the DSCI.

The SBIU provides an interface between the QSMCM module and the intermodule bus (IMB3).

### 15.1 Block Diagram

Figure 15-1 shows the major components of the QSMCM.

Note: SBIU bus and interface to IMB3 are each 16 bits wide.

**Figure 15-1. QSMCM Block Diagram**

## 15.2 Key Features

Standard SPI features are listed below, followed by a list of the additional features offered on the QSPI:

- Full-duplex, three-wire synchronous transfers
- Half-duplex, two-wire synchronous transfers
- Master or slave operation on the SPI bus
- Programmable master bit rates
- Programmable clock polarity and phase
- End-of-transmission interrupt flag
- Master-master mode fault flag
- Easily interfaces to simple expansion parts (A/D converters, EEPROMS, display drivers, etc.)

QSPI-enhanced features are as follows:

- Programmable Queue — up to 32 preprogrammed transfers
- Programmable Peripheral Chip-Selects — four pins select up to 16 SPI chips
- Wraparound Transfer Mode — for autoscanning of serial A/D (or other) peripherals, with no CPU overhead
- Programmable Transfer Length — from 8–16 bits inclusive

- Programmable Transfer Delay — from 0.6  $\mu$ s to 0.3  $\mu$ s (at 28 MHz)
- Programmable Queue Pointer
- Continuous Transfer Mode — up to 256 bits
- Optional on-chip expanded QSPI chip selects

Standard SCI features are listed below, followed by a list of additional features offered.

Standard SCI two-wire system features:

- Standard nonreturn-to-zero (NRZ) mark/space format
- Advanced error detection mechanism (detects noise duration up to 1/16 of a bit-time)
- Full-duplex operation
- Software selectable word length (8- or 9-bit words)
- Separate transmitter and receiver enable bits
- May be interrupt driven
- Four separate interrupt enable bits
- Two independent operating SCI modules

Standard SCI receiver features:

- Receiver wakeup function (idle or address mark bit)
- Idle-line detect
- Framing, noise, and overrun error detect
- Receive data register full flag

Standard SCI transmitter features:

- Transmit data register empty flag
- Transmit complete flag
- Send break

QSMCM-additional SCI features:

- 13-bit programmable baud-rate modulus counter
- Even/odd parity generation and detection
- Two idle-line detect modes
- Receiver active flag

QSMCM-enhanced SCI features:

- 16 register receive buffer on one SCI
- 16 register transmit buffer on one SCI

### 15.2.1 MPC561/MPC563 QSMCM Details

The QSMCM module has an identical function to the MPC555. The MUXing of the pins is controlled by the QPAPCS3 bit in the QSMCM pin assignment register (PQSPAR).

## 15.3 Memory Maps

The QSMCM memory maps, shown in [Table 15-1](#) and [Table 15-2](#), includes the global registers, the QSPI and dual SCI control and status registers, and the QSPI RAM. The QSMCM memory map can be divided into supervisor-only data space and assignable data space. The address offsets shown are from the base address of the QSMCM module. Refer to [Figure 1-4](#) for a diagram of the MPC561/MPC563 internal memory map.

<sup>1</sup> S = Supervisor access only

S/U = Supervisor access only or unrestricted user access (assignable data space).

<sup>2</sup> 8-bit registers, such as SPCR3 and SPSR, are on 8-bit boundaries. 16-bit registers such as SPCR0 are on 16-bit boundaries.

<sup>3</sup> Note that QRAM offsets have been changed from the original (modular family) QSMCM.

The supervisor-only data space segment contains the QSMCM global registers. These registers define parameters needed by the QSMCM to integrate with the MCU. Access to these registers is permitted only when the CPU is operating in supervisor mode.

Assignable data space can be either restricted to supervisor-only access or unrestricted to both supervisor and user accesses. The supervisor (SUPV) bit in the QSMCM module configuration register (QSMCMCR) designates the assignable data space as either supervisor or unrestricted. If SUPV is set, then the space is designated as supervisor-only space. Access is then permitted only when the CPU is operating in supervisor mode. If SUPV is clear, both user and supervisor accesses are permitted. To clear SUPV, the CPU must be in supervisor mode.

The QSMCM assignable data space segment contains the control and status registers for the QSPI and SCI submodules, as well as the QSPI RAM. All registers and RAM can be accessed on byte (8-bits), half-word (16-bits), and word (32-bit) boundaries. Word accesses require two consecutive IMB3 bus cycles.

## 15.4 QSMCM Global Registers

The QSMCM global registers contain system parameters used by the QSPI and dual SCI submodules for interfacing to the CPU and the intermodule bus. The global registers are listed in [Table 15-2](#).

**Table 15-2. QSMCM Global Registers**

| Access <sup>1</sup> | Address   | MSB <sup>2</sup><br>0                                                                            | LSB<br>15                                                                              |

| S                   | 0x30 5006 | Reserved                                                                                         | Queued SPI Interrupt Level (QSPI_IL)<br>See <XrefBlue>Table 15-6 for bit descriptions. |

<sup>1</sup> S = Supervisor access only

S/U = Supervisor access only or unrestricted user access (assignable data space).

<sup>2</sup> 8-bit registers reside on 8-bit boundaries. 16-bit registers reside on 16-bit boundaries.

### 15.4.1 Low-Power Stop Operation

When the STOP bit in QSMCMMCR is set, the IMB3 clock input to the QSMCM is disabled and the module enters a low-power operating state. QSMCMMCR is the only register guaranteed to be readable while STOP is asserted. The QSPI RAM is not readable in low-power stop mode. However, writes to RAM or any register are guaranteed valid while STOP is asserted. STOP can be written by the CPU and is cleared by reset.

System software must bring each submodule to an orderly stop before setting STOP to avoid data corruption. The SCI receiver and transmitter should be disabled after transfers in progress are complete. The QSPI can be halted by setting the HALT bit in SPCR3 and then setting STOP after the HALTA flag is set in SPSR.

### 15.4.2 Freeze Operation

The FRZ1 bit in QSMCMMCR determines how the QSMCM responds when the IMB3 FREEZE signal is asserted. FREEZE is asserted when the CPU enters background debug mode. Setting FRZ1 causes the QSPI to halt on the first transfer boundary following FREEZE assertion. FREEZE causes the SCI1 transmit queue to halt on the first transfer boundary following FREEZE assertion.

### 15.4.3 Access Protection

The SUPV bit in the QMCR defines the assignable QSMCM registers as either supervisor-only data space or unrestricted data space.

When the SUPV bit is set, all registers in the QSMCM are placed in supervisor-only space. For any access from within user mode, the IMB3 address acknowledge (AACK) signal is asserted and a bus error is generated.

Because the QSMCM contains a mix of supervisor and user registers,  $\overline{AACK}$  is asserted for either supervisor or user mode accesses, and the bus cycle remains internal. If a supervisor-only register is accessed in user mode, the module responds as if an access had been made to an unauthorized register location, and a bus error is generated.

### 15.4.4 QSMCM Interrupts

The interrupt structure of the IMB3 supports a total of 32 interrupt levels that are time multiplexed on the  $\overline{IRQB}[0:7]$  lines as seen in Figure 15-2.

Figure 15-2. QSMCM Interrupt Levels

In this structure, all interrupt sources place their asserted level on a time multiplexed bus during four different time slots, with eight levels communicated per slot. The ILBS[0:1] signals indicate which group of eight are being driven on the interrupt request lines.

Table 15-3. Interrupt Levels

| ILBS[0:1] | Levels |
|-----------|--------|
| 00        | 0:7    |
| 01        | 8:15   |
| 10        | 16:23  |
| 11        | 24:31  |

The QSMCM module is capable of generating one of the 32 possible interrupt levels on the IMB3. The levels that the interrupt will drive can be programmed into the interrupt request level (ILDSCI and ILQSPI) bits located in the interrupt configuration register (QDSCI\_IL and QSPI\_IL). This value determines which interrupt signal ( $\overline{IRQB}[0:7]$ ) is driven onto the bus during the programmed time slot. Figure 15-3 shows a block diagram of the interrupt hardware.

Figure 15-3. Interrupt Hardware Block Diagram

### 15.4.5 QSPI Interrupt Generation

### 15.4.6 QSMCM Configuration Register (QSMCMMCR)

The QSMCMMCR contains parameters for interfacing to the CPU and the intermodule bus. This register can be modified only when the CPU is in supervisor mode.

## 15.4.7 QSMCM Test Register (QTEST)

The QTEST register is used for factory testing of the MCU.

## 15.4.8 QSMCM Interrupt Level Registers (QDSCI\_IL, QSPI\_IL)

The QDSCI\_ILI and QSPI\_IL registers determine the interrupt level requested by the QSMCM. The two SCI submodules (DSCI) share a 5-bit interrupt level field, ILDSCI. The QSPI uses a separate field, ILQSPI. The level value is used to determine which interrupt is serviced first when two or more modules or external peripherals simultaneously request an interrupt. The user can select among 32 levels. This register can be accessed only when the CPU is in supervisor mode.

## 15.5 QSMCM Pin Control Registers

Table 15-7 lists the three QSMCM pin control registers.

**Table 15-7. QSMCM Pin Control Registers**

| Address   | Register                                                                                                       |
|-----------|----------------------------------------------------------------------------------------------------------------|
| 0x30 5014 | QSMCM Port Data Register (PORTQS)<br>See Section 15.5.1, "Port QS Data Register (PORTQS) for bit descriptions. |
| 0x30 5016 | PORTQS Pin Assignment Register (PQSPAR)<br>See <XrefBlue>Table 15-10 for bit descriptions.                     |
| 0x30 5017 | PORTQS Data Direction Register (DDRQS)<br>See <XrefBlue>Table 15-10 for bit descriptions.                      |

The QSMCM uses 11 pins. These pins, when not being used by the serial sub-systems, form a parallel port on the MCU.

The port QS pin assignment register (PQSPAR) governs the usage of QSPI pins. Clearing a bit assigns the corresponding pin to general-purpose I/O; setting a bit assigns the pin to the QSPI.

PQSPAR does not affect operation of the SCI. When the SCIx transmitter is disabled, TXDx is a discrete output; when the SCIx receiver is disabled, RXDx is a discrete input. When the SCIx transmitter or receiver is enabled, the associated TXDx or RXDx pin is assigned its SCI function.

The port QS data direction register (DDRQS) determines whether QSPI pins are inputs or outputs. Clearing a bit makes the corresponding pin an input; setting a bit makes the pin an output. DDRQS affects both QSPI function and I/O function. Table 15-8 summarizes the effect of DDRQS bits on QSPI pin function.

DDRQS does not affect SCI pin function. TXDx pins are always outputs, and RXDx pins are always inputs, regardless of whether they are functioning as SCI pins or as PORTQS pins.

The port QS data register (PORTQS) latches I/O data. PORTQS writes drive pins defined as outputs. PORTQS reads return data present on the pins. To avoid driving undefined data, write the first data to PORTQS before configuring DDRQS.

**Table 15-8. Effect of DDRQS on QSPI Pin Function**

| QSMCM Pin             | Mode   | DDRQS Bit | Bit State | Pin Function                 |
|-----------------------|--------|-----------|-----------|------------------------------|
| MISO                  | Master | DDQS0     | 0         | Serial data input to QSPI    |
|                       |        |           | 1         | Disables data input          |
|                       | Slave  |           | 0         | Disables data output         |
|                       |        |           | 1         | Serial data output from QSPI |
| MOSI                  | Master | DDQS1     | 0         | Disables data output         |

<sup>1</sup> SCK/QGPIO6 is a digital I/O pin unless the SPI is enabled (SPE set in SPCR1), in which case it becomes the QSPI serial clock SCK.

### 15.5.1 Port QS Data Register (PORTQS)

PORTQS determines the actual input or output value of a QSMCM port pin if the pin is defined as general-purpose input or output. All QSMCM pins can be used as general-purpose input and/or output. When the SCIx transmitter is disabled, TXDx is a discrete output; when the SCIx receiver is disabled, RXDx is a discrete input. Writes to this register affect the pins defined as outputs; reads of this register return the actual value of the pins.

#### NOTE

The PORTQS register can be written either as a half-word (16-bit) or as 2 individual bytes (8-bit). This allows the SCI GPIO pin data to be written separately than the QSPI GPIO pin values. This allows either the SCI pins or the QSPI pins to be used independently as GPIO.

### 15.5.2 PORTQS Pin Assignment Register (PQSPAR)

PQSPAR determines which of the QSPI pins, with the exception of the SCK pin, are used by the QSPI submodule, and which pins are available for general-purpose I/O. Pins may be assigned on a pin-by-pin basis. If the QSPI is disabled, the SCK pin is automatically assigned its general-purpose I/O function (QGPI06).

QSPI pins designated by PQSPAR as general-purpose I/O pins are controlled only by PQSDDR and PQSPDR; the QSPI has no effect on these pins. PQSPAR does not affect the operation of the SCI submodule.

Table 15-9 summarizes the QSMCM pin functions.

Table 15-9. QSMCM Pin Functions

| PORTQS Function | QSMCM Function | Alternate Function |
|-----------------|----------------|--------------------|
| QGPI2           | RXD2           | C_CNRX0            |

### 15.5.3 PORTQS Data Direction Register (DDRQS)

DDRQS assigns QSPI pin as an input or an output regardless of whether the QSPI submodule is enabled or disabled. All QSPI pins are configured during reset as general-purpose inputs.

This register does not affect SCI operation. The TXD1 and TXD2 remain output pins dedicated to the SCI submodules, and the RXD1 and RXD2 pins remain input pins dedicated to the SCI submodules.

## 15.6 Queued Serial Peripheral Interface

The queued serial peripheral interface (QSPI) is used to communicate with external devices through a synchronous serial bus. The QSPI is fully compatible with SPI systems found on other Freescale products, but has enhanced capabilities. The QSPI can perform full duplex three-wire or half duplex two-wire transfers. Several transfer rates, clocking, and interrupt-driven communication options are available. [Figure 15-10](#) is a block diagram of the QSPI.

QSPI Block

Figure 15-10. QSPI Block Diagram

Serial transfers of eight to 16 bits can be specified. Programmable transfer length simplifies interfacing to devices that require different data lengths.

An inter-transfer delay of approximately 0.8 to 204  $\mu\text{s}$  (using a 40-MHz IMB3 clock) can be programmed. The default delay is 17 clocks (0.425  $\mu\text{s}$  at 40 MHz). Programmable delay simplifies the interface to devices that require different delays between transfers.

A dedicated 160-byte RAM is used to store received data, data to be transmitted, and a queue of commands. The CPU can access these locations directly. This allows serial peripherals to be treated like memory-mapped parallel devices.

The command queue allows the QSPI to perform up to 32 serial transfers without CPU intervention. Each queue entry contains all the information needed by the QSPI to independently complete one serial transfer.

A pointer identifies the queue location containing the data and command for the next serial transfer. Normally, the pointer address is incremented after each serial transfer, but the CPU can change the pointer value at any time. Support for multiple-tasks can be provided by segmenting the queue.

The QSPI has four peripheral chip-select pins. The chip-select signals simplify interfacing by reducing CPU intervention. If the chip-select signals are externally decoded, 16 independent select signals can be generated.

Wrap-around mode allows continuous execution of queued commands. In wraparound mode, newly received data replaces previously received data in the receive RAM. Wrap-around mode can simplify the interface with A/D converters by continuously updating conversion values stored in the RAM.

Continuous transfer mode allows transfer of an uninterrupted bit stream. From 8 to 512 bits can be transferred without CPU intervention. Longer transfers are possible, but minimal intervention is required to prevent loss of data. A standard delay of 17 IMB3 clocks (0.8  $\mu$ s with a 40-MHz IMB3 clock) is inserted between the transfer of each queue entry.

### 15.6.1 QSPI Registers

The QSPI memory map, shown in [Table 15-12](#), includes the QSMCM global and pin control registers, four QSPI control registers (SPCR[0:3]), the status register (SPSR), and the QSPI RAM. Registers and RAM can be read and written by the CPU. The memory map can be divided into supervisor-only data space and assignable data space. The address offsets shown are from the base address of the QSMCM module. Refer to [Figure 1-4](#) for a diagram of the MPC561/MPC563 internal memory map.

**Table 15-12. QSPI Register Map**

| Access <sup>1</sup> | Address                  | MSB <sup>2</sup><br>0                                                              | LSB<br>15                                                                      |

**Table 15-12. QSPI Register Map (continued)**

| Access <sup>1</sup> | Address                  | MSB <sup>2</sup><br>0             | LSB<br>15 |
|---------------------|--------------------------|-----------------------------------|-----------|
| S/U                 | 0x30 5180 –<br>0x30 51BF | Transmit Data RAM (32 half-words) |           |
| S/U                 | 0x30 51C0 –<br>0x30 51DF | Command RAM (32 bytes)            |           |

<sup>1</sup> S = Supervisor access only

S/U = Supervisor access only or unrestricted user access (assignable data space).

<sup>2</sup> Eight-bit registers, such as SPCR3 and SPSR, are on 8-bit boundaries. 16-bit registers such as SPCR0 are on 16-bit boundaries.

To ensure proper operation, set the QSPI enable bit (SPE) in SPCR1 only after initializing the other control registers. Setting this bit starts the QSPI.

Rewriting the same value to a control register does not affect QSPI operation with the exception of writing NEWQP in SPCR2. Rewriting the same value to these bits causes the RAM queue pointer to restart execution at the designated location.

Before changing control bits, the QSPI should be halted. Writing a different value into a control register other than SPCR2 while the QSPI is enabled may disrupt operation. SPCR2 is buffered, preventing any disruption of the current serial transfer. After the current serial transfer is completed, the new SPCR2 value becomes effective.

### 15.6.1.1 QSPI Control Register 0 (SPCR0)

SPCR0 contains parameters for configuring the QSPI before it is enabled. The CPU has read/write access to SPCR0, but the QSPI has read access only. SPCR0 must be initialized before QSPI operation begins. Writing a new value to SPCR0 while the QSPI is enabled disrupts operation.

**Table 15-13. SPCR0 Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|------|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | MSTR | Master/slave mode select<br>0 QSPI is a slave device and only responds to externally generated serial transfers.<br>1 QSPI is the system master and can initiate transmission to external SPI devices.                                                                                                                                                                                                                                                                                                                                     |
| 1    | WOMQ | Wired-OR mode for QSPI pins. This bit controls the QSPI pins regardless of whether they are used as general-purpose outputs or as QSPI outputs, and regardless of whether the QSPI is enabled or disabled.<br>0 Pins designated for output by DDRQS operate in normal mode.<br>1 Pins designated for output by DDRQS operate in open drain mode.                                                                                                                                                                                           |
| 2:5  | BITS | Bits per transfer. In master mode, when BITSE is set in a command RAM byte, BITS determines the number of data bits transferred. When BITSE is cleared, eight bits are transferred regardless of the value in BITS. In slave mode, the BITS field always determines the number of bits the QSPI will receive during each transfer before storing the received data.<br>Data transfers from 8 to 16 bits are supported. Illegal (reserved) values default to eight bits. <a href="#">Table 15-14</a> shows the number of bits per transfer. |
| 6    | CPOL | Clock polarity. CPOL is used to determine the inactive state of the serial clock (SCK). It is used with CPHA to produce a desired clock/data relationship between master and slave devices.<br>0 The inactive state of SCK is logic zero.<br>1 The inactive state of SCK is logic one.                                                                                                                                                                                                                                                     |
| 7    | CPHA | Clock phase. CPHA determines which edge of SCK causes data to change and which edge causes data to be captured. CPHA is used with CPOL to produce a desired clock/data relationship between master and slave devices.<br>0 Data is captured on the leading edge of SCK and changed on the trailing edge of SCK.<br>1 Data is changed on the leading edge of SCK and captured on the trailing edge of SCK                                                                                                                                   |
| 8:15 | SPBR | Serial clock baud rate. The QSPI uses a modulus counter to derive the SCK baud rate from the MCU IMB3 clock. Baud rate is selected by writing a value from 2 to 255 into SPBR. The following equation determines the SCK baud rate:<br><br>$\text{SCK Baud Rate} = \frac{f_{\text{SYS}}}{2 \times \text{SPBR}}$<br><br>Refer to <a href="#">Section 15.6.5.2, “Baud Rate Selection”</a> for more information.                                                                                                                              |

| 1111      | 15                |

### 15.6.1.2 QSPI Control Register 1 (SPCR1)

SPCR1 enables the QSPI and specifies transfer delays. The CPU has read/write access to SPCR1, but the QSPI has read access only to all bits except SPE. SPCR1 must be written last during initialization because it contains SPE. The QSPI automatically clears this bit after it completes all serial transfers or when a mode fault occurs. Writing a new value to SPCR1 while the QSPI is enabled disrupts operation.

Figure 15-12. SPCR1 — QSPI Control Register

Table 15-15. SPCR1 Bit Descriptions

| Bits | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|------|-------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | SPE   | QSPI enable. Refer to Section 15.6.4.1, “Enabling, Disabling, and Halting the SPI.<br>0 = QSPI is disabled. QSPI pins can be used for general-purpose I/O.<br>1 = QSPI is enabled. Pins allocated by PQSPAR are controlled by the QSPI.                                                                                                                                                                                                                                                                                                            |
| 1:7  | DSCKL | Delay before SCK. When the DSCKL bit is set in a command RAM byte, this field determines the length of the delay from PCS valid to SCK transition. The following equation determines the actual delay before SCK:<br>$\text{PCS to SCK Delay} = \frac{\text{DSCKL}}{f_{\text{SYS}}}$<br>where DSCKL equals is in the range of 1 to 127.<br>Refer to Section 15.6.5.3, “Delay Before Transfer for more information.                                                                                                                                 |
| 8:15 | DTL   | Length of delay after transfer. When the DT bit is set in a command RAM byte, this field determines the length of the delay after a serial transfer. The following equation is used to calculate the delay:<br>$\text{Delay after Transfer} = \frac{32 \times \text{DTL}}{f_{\text{SYS}}}$<br>where DTL is in the range of 1 to 255.<br>A zero value for DTL causes a delay-after-transfer value of $8192 \div f_{\text{SYS}}$ (204.8 $\mu$ s with a 40-MHz IMB3 clock).<br>Refer to Section 15.6.5.4, “Delay After Transfer for more information. |

### 15.6.1.3 QSPI Control Register 2 (SPCR2)

SPCR2 contains QSPI queue pointers, wraparound mode control bits, and an interrupt enable bit. The CPU has read/write access to SPCR2, but the QSPI has read access only. Writes to this register are buffered. New SPCR2 values become effective only after completion of the current serial transfer. Rewriting NEWQP in SPCR2 causes execution to restart at the designated location. Reads of SPCR2 return the current value of the register, not the buffer.

|-------|--------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0     | SPIFIE | SPI finished interrupt enable. Refer to <a href="#">Section 15.6.4.2, “QSPI Interrupts.”</a><br>0 QSPI interrupts disabled<br>1 QSPI interrupts enabled                                                                                                                                                                                                                                                                                 |
| 1     | WREN   | Wrap enable. Refer to <a href="#">Section 15.6.5.8, “Master Wraparound Mode.”</a><br>0 Wraparound mode disabled.<br>1 Wraparound mode enabled.                                                                                                                                                                                                                                                                                          |
| 2     | WRT0   | Wrap to. When wraparound mode is enabled and after the end of queue has been reached, WRT0 determines which address the QSPI executes next. The end of queue is determined by an address match with ENDQP.<br>0 Wrap to pointer address 0x0<br>1 Wrap to address in NEWQP                                                                                                                                                               |
| 3:7   | ENDQP  | Ending queue pointer. This field determines the last absolute address in the queue to be completed by the QSPI. After completing each command, the QSPI compares the queue pointer value of the just-completed command with the value of ENDQP. If the two values match, the QSPI sets SPIF to indicate it has reached the end of the programmed queue. Refer to <a href="#">Section 15.6.4, “QSPI Operation”</a> for more information. |
| 8:10  | —      | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 11:15 | NEWQP  | New queue pointer value. This field contains the first QSPI queue address. Refer to <a href="#">Section 15.6.4, “QSPI Operation”</a> for more information.                                                                                                                                                                                                                                                                              |

### 15.6.1.4 QSPI Control Register 3 (SPCR3)

SPCR3 contains the loop mode enable bit, halt and mode fault interrupt enable, and the halt control bit. The CPU has read/write access to SPCR3, but the QSPI has read access only. SPCR3 must be initialized before QSPI operation begins. Writing a new value to SPCR3 while the QSPI is enabled disrupts operation.

| 0:4  | —     | Reserved                                                                                                                                                                                                                                                                                             |
| 5    | LOOPQ | QSPI loop mode. LOOPQ controls feedback on the data serializer for testing.<br>0 Feedback path disabled.<br>1 Feedback path enabled.                                                                                                                                                                 |
| 6    | HMIE  | HALTA and MODF interrupt enable. HMIE enables interrupt requests generated by the HALTA status flag or the MODF status flag in SPSR.<br>0 HALTA and MODF interrupts disabled.<br>1 HALTA and MODF interrupts enabled.                                                                                |
| 7    | HALT  | Halt QSPI. When HALT is set, the QSPI stops on a queue boundary. It remains in a defined state from which it can later be restarted. Refer to <a href="#">Section 15.6.4.1, “Enabling, Disabling, and Halting the SPI.”</a><br>0 QSPI operates normally.<br>1 QSPI is halted for subsequent restart. |
| 8:15 | SPSR  | See <a href="#">Table 15-18</a> for bit descriptions.                                                                                                                                                                                                                                                |

### 15.6.1.5 QSPI Status Register (SPSR)

The SPSR contains information concerning the current serial transmission. Only the QSPI can set bits in this register. To clear status flags, the CPU reads SPSR with the flags set and then writes the SPSR with zeros in the appropriate bits. Writes to CPTQP have no effect.

| MSB                        |                               |   |   |   |   |   |   |   |      |      |       |       |    |    |    | LSB |

| Bits  | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|-------|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7   | SPCR3 | See bit descriptions in <a href="#">Table 15-17</a> .                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 8     | SPIF  | QSPI finished flag. SPIF is set after execution of the command at the address in ENDQP in SPCR2. If wraparound mode is enabled (WREN = 1), the SPIF is set, after completion of the command defined by ENDQP, each time the QSPI cycles through the queue.<br>0 QSPI is not finished<br>1 QSPI is finished                                                                                                                                                                                                        |
| 9     | MODF  | Mode fault flag. The QSPI asserts MODF when the QSPI is in master mode (MSTR = 1) and the $\overline{SS}$ input pin is negated by an external driver. Refer to <a href="#">Section 15.6.8, “Mode Fault”</a> for more information.<br>0 Normal operation<br>1 Another SPI node requested to become the network SPI master while the QSPI was enabled in master mode ( $\overline{SS}$ input taken low).                                                                                                            |
| 10    | HALTA | Halt acknowledge flag. HALTA is set when the QSPI halts in response to setting the HALT bit in SPCR3. HALTA is also set when the IMB3 FREEZE signal is asserted, provided the FRZ1 bit in the QSMCMMCR is set. To prevent undefined operation, no modification should be made to any QSPI control registers or RAM while the QSPI is halted.<br>If HMIE in SPCR3 is set the QSPI sends interrupt requests to the CPU when HALTA is asserted.<br>0 QSPI is not halted.<br>1 QSPI is halted                         |
| 11:15 | CPTQP | Completed queue pointer. CPTQP points to the last command executed. It is updated when the current command is complete. When the first command in a queue is executing, CPTQP contains either the reset value 0x0 or a pointer to the last command completed in the previous queue. If the QSPI is halted, CPTQP may be used to determine which commands have not been executed. The CPTQP may also be used to determine which locations in the receive data segment of the QSPI RAM contain valid received data. |

## 15.6.2 QSPI RAM

The QSPI contains a 160-byte block of dual-ported static RAM that can be accessed by both the QSPI and the CPU. Because of this dual access capability, up to two wait states may be inserted into CPU access time if the QSPI is in operation.

The size and type of access of the QSPI RAM by the CPU affects the QSPI access time. The QSPI allows byte, half-word, and word accesses. Only word accesses of the RAM by the CPU are coherent because these accesses are an indivisible operation. If the CPU makes a coherent access of the QSPI RAM, the QSPI cannot access the QSPI RAM until the CPU is finished. However, a word or misaligned word access is not coherent because the CPU must break its access of the QSPI RAM into two parts, which allows the QSPI to access the QSPI RAM between the two accesses by the CPU.

The RAM is divided into three segments: receive data RAM, transmit data RAM, and command data RAM. Receive data is information received from a serial device external to the MCU. Transmit data is information stored for transmission to an external device. Command data defines transfer parameters. [Figure 15-16](#) shows RAM organization.

**Figure 15-16. QSPI RAM**

### 15.6.2.1 Receive RAM

Data received by the QSPI is stored in this segment, to be read by the CPU. Data stored in the receive RAM is right-justified, (i.e., the least significant bit is always in the right-most bit position within the word regardless of the serial transfer length). Unused bits in a receive queue entry are set to zero by the QSPI upon completion of the individual queue entry. The CPU can access the data using byte, half-word, or word addressing.

The CPTQP value in SPSR shows which queue entries have been executed. The CPU uses this information to determine which locations in receive RAM contain valid data before reading them.

### 15.6.2.2 Transmit RAM

Data that is to be transmitted by the QSPI is stored in this segment. The CPU normally writes one word of data into this segment for each queue command to be executed. If the corresponding peripheral, such as a serial input port, is used solely to input data, then this segment does not need to be initialized.

Data must be written to transmit RAM in a right-justified format. The QSPI cannot modify information in the transmit RAM. The QSPI copies the information to its data serializer for transmission. Information remains in transmit RAM until overwritten.

### 15.6.2.3 Command RAM

Command RAM is used by the QSPI in master mode. The CPU writes one byte of control information to this segment for each QSPI command to be executed. The QSPI cannot modify information in command RAM.

Command RAM consists of 32 bytes. Each byte is divided into two fields. The peripheral chip-select field, enables peripherals for transfer. The command control field provides transfer options.

A maximum of 32 commands can be in the queue. These bytes are assigned an address from 0x00 to 0x1F. Queue execution by the QSPI proceeds from the address in NEWQP through the address in ENDQP. (Both of these fields are in SPCR2.)

| MSB  |       |    |      |      |      |      | LSB               |

| 4:7  | PCS[3:0] | Peripheral chip selects. Use peripheral chip-select bits to select an external device for serial data transfer. More than one peripheral chip select may be activated at a time, and more than one peripheral chip can be connected to each PCS pin, provided proper fanout is observed. PCS0 shares a pin with the slave select ( $\overline{\text{SS}}$ ) signal, which initiates slave mode serial transfer. If $\overline{\text{SS}}$ is taken low when the QSPI is in master mode, a mode fault occurs. |

Refer to [Section 15.6.5, “Master Mode Operation”](#) for more information on the command RAM.

### 15.6.3 QSPI Pins

Seven pins are associated with the QSPI. When not needed by the QSPI, they can be configured for general-purpose I/O. [Table 15-20](#) identifies the QSPI pins and their functions. Register DDRQS determines whether the pins are designated as input or output. The user must initialize DDRQS for the QSPI to function correctly.

Table 15-20. QSPI Pin Functions

| Pin Names                                                        | Mnemonic                         | Mode            | Function                                                  |
|------------------------------------------------------------------|----------------------------------|-----------------|-----------------------------------------------------------|
| Master in slave out                                              | $\overline{\text{MISO}}$         | Master<br>Slave | Serial data input to QSPI<br>Serial data output from QSPI |
| Master out slave in                                              | $\overline{\text{MOSI}}$         | Master<br>Slave | Serial data output from QSPI<br>Serial data input to QSPI |
| Serial clock                                                     | SCK <sup>1</sup>                 | Master<br>Slave | Clock output from QSPI clock<br>Input to QSPI             |
| Peripheral chip selects                                          | PCS[1:3]                         | Master          | Outputs select peripheral(s)                              |
| Peripheral chip select <sup>2</sup><br>Slave select <sup>3</sup> | PCS0 /<br>$\overline{\text{SS}}$ | Master<br>Slave | Output selects peripheral(s)<br>Input selects the QSPI    |
| Slave select <sup>4</sup>                                        | $\overline{\text{SS}}$           | Master          | May cause mode fault                                      |

<sup>1</sup> All QSPI pins (except SCK) can be used as general-purpose I/O if they are not used by the QSPI while the QSPI is operating. SCK can only be used for general-purpose I/O if the QSPI is disabled.

<sup>2</sup> An output (PCS0) when the QSPI is in master mode.

<sup>3</sup> An input ( $\overline{\text{SS}}$ ) when the QSPI is in slave mode.

<sup>4</sup> An input ( $\overline{\text{SS}}$ ) when the QSPI is in master mode; useful in multimaster systems.

## 15.6.4 QSPI Operation

The QSPI uses a dedicated 160-byte block of static RAM accessible by both the QSPI and the CPU to perform queued operations. The RAM is divided into three segments: 32 command control bytes, 64 transmit data bytes, and 64 receive data bytes.

Once the CPU has set up a queue of QSPI commands, written the transmit data segment with information to be sent, and enabled the QSPI, the QSPI operates independently of the CPU. The QSPI executes all of the commands in its queue, sets a flag indicating completion, and then either interrupts the CPU or waits for CPU intervention.

QSPI RAM is organized so that one byte of command data, one word of transmit data, and one word of receive data correspond to each queue entry, 0x0 to 0x2F.

The CPU initiates QSPI operation by setting up a queue of QSPI commands in command RAM, writing transmit data into transmit RAM, then enabling the QSPI. The QSPI executes the queued commands, sets a completion flag (SPIF), and then either interrupts the CPU or waits for intervention.

There are four queue pointers. The CPU can access three of them through fields in QSPI registers. The new queue pointer (NEWQP), contained in SPCR2, points to the first command in the queue. An internal queue pointer points to the command currently being executed. The completed queue pointer (CPTQP), contained in SPSR, points to the last command executed. The end queue pointer (ENDQP), contained in SPCR2, points to the final command in the queue.

The internal pointer is initialized to the same value as NEWQP. During normal operation, the command pointed to by the internal pointer is executed, the value in the internal pointer is copied into CPTQP, the internal pointer is incremented, and then the sequence repeats. Execution continues at the internal pointer address unless the NEWQP value is changed. After each command is executed, ENDQP and CPTQP are

compared. When a match occurs, the SPIF flag is set and the QSPI stops and clears SPE, unless wraparound mode is enabled.

At reset, NEWQP is initialized to 0x0. When the QSPI is enabled, execution begins at queue address 0x0 unless another value has been written into NEWQP. ENDQP is initialized to 0x0 at reset but should be changed to the last queue entry before the QSPI is enabled. NEWQP and ENDQP can be written at any time. When NEWQP changes, the internal pointer value also changes. However, if NEWQP is written while a transfer is in progress, the transfer is completed normally. Leaving NEWQP and ENDQP set to 0x0 transfers only the data in transmit RAM location 0x0.

#### 15.6.4.1 Enabling, Disabling, and Halting the SPI

The SPE bit in the SPCR1 enables or disables the QSPI submodule. Setting SPE causes the QSPI to begin operation. If the QSPI is a master, setting SPE causes the QSPI to begin initiating serial transfers. If the QSPI is a slave, the QSPI begins monitoring the PCS0/ $\overline{SS}$  pin to respond to the external initialization of a serial transfer.

When the QSPI is disabled, the CPU may use the QSPI RAM. When the QSPI is enabled, both the QSPI and the CPU have access to the QSPI RAM. The CPU has both read and write access to all 160 bytes of the QSPI RAM. The QSPI can read-only the transmit data segment and the command control segment and can write-only the receive data segment of the QSPI RAM.

The QSPI turns itself off automatically when it is finished by clearing SPE. An error condition called mode fault (MODF) also clears SPE. This error occurs when PCS0/ $\overline{SS}$  is configured for input, the QSPI is a system master (MSTR = 1), and PCS0/ $\overline{SS}$  is driven low externally.

Setting the HALT bit in SPCR3 stops the QSPI on a queue boundary. The QSPI halts in a known state from which it can later be restarted. When HALT is set, the QSPI finishes executing the current serial transfer (up to 16 bits) and then halts. While halted, if the command control bit (CONT of the QSPI RAM) for the last command was asserted, the QSPI continues driving the peripheral chip select pins with the value designated by the last command before the halt. If CONT was cleared, the QSPI drives the peripheral chip-select pins to the value in register PORTQS.

If HALT is set during the last command in the queue, the QSPI completes the last command, sets both HALTA and SPIF, and clears SPE. If the last queue command has not been executed, asserting HALT does not set SPIF or clear SPE. QSPI execution continues when the CPU clears HALT.

To stop the QSPI, assert the HALT bit in SPCR3, then wait until the HALTA bit in SPSR is set. SPE can then be safely cleared, providing an orderly method of shutting down the QSPI quickly after the current serial transfer is completed. The CPU can disable the QSPI immediately by clearing SPE. However, loss of data from a current serial transfer may result and confuse an external SPI device.

#### 15.6.4.2 QSPI Interrupts

The QSPI has three possible interrupt sources but only one interrupt vector. These sources are SPIF, MODF, and HALTA. When the CPU responds to a QSPI interrupt, the interrupt cause must be ascertained by reading the SPSR. Any interrupt that was set may then be cleared by writing to SPSR with a zero in the bit position corresponding to the interrupt source.

The SPIFIE bit in SPCR2 enables the QSPI to generate an interrupt request upon assertion of the SPIF status flag. Because it is buffered, the value written to SPIFIE applies only upon completion of the queue (the transfer of the entry indicated by ENDPQ). Thus, if a single sequence of queue entries is to be transferred (i.e., no WRAP), then SPIFIE should be set to the desired state before the first transfer.

If a sub-queue is to be used, the same CPU write that causes a branch to the sub-queue may enable or disable the SPIF interrupt for the sub-queue. The primary queue retains its own selected interrupt mode, either enabled or disabled.

The SPIF interrupt must be cleared by clearing SPIF. Subsequent interrupts may then be prevented by clearing SPIFIE. Clearing SPIFIE does not immediately clear an interrupt already caused by SPIF.

### 15.6.4.3 QSPI Flow

The QSPI operates in either master or slave mode. Master mode is used when the MCU initiates data transfers. Slave mode is used when an external device initiates transfers. Switching between these modes is controlled by MSTR in SPCR0. Before entering either mode, appropriate QSMCM and QSPI registers must be initialized properly.

In master mode, the QSPI executes a queue of commands defined by control bits in each command RAM queue entry. Chip-select pins are activated, data is transmitted from the transmit RAM and received by the receive RAM.

In slave mode, operation proceeds in response to  $\overline{SS}$  pin assertion by an external SPI bus master. Operation is similar to master mode, but no peripheral chip selects are generated, and the number of bits transferred is controlled in a different manner. When the QSPI is selected, it automatically executes the next queue transfer to exchange data with the external device correctly.

Although the QSPI inherently supports multi-master operation, no special arbitration mechanism is provided. A mode fault flag (MODF) indicates a request for SPI master arbitration. System software must provide arbitration. Note that unlike previous SPI systems, MSTR is not cleared by a mode fault being set nor are the QSPI pin output drivers disabled. The QSPI and associated output drivers must be disabled by clearing SPE in SPCR1.

Figure 15-18 shows QSPI initialization. Figure 15-19 through Figure 15-23 show QSPI master and slave operation. The CPU must initialize the QSMCM global and pin registers and the QSPI control registers before enabling the QSPI for either mode of operation. The command queue must be written before the QSPI is enabled for master mode operation. Any data to be transmitted should be written into transmit RAM before the QSPI is enabled. During wraparound operation, data for subsequent transmissions can be written at any time.

Figure 15-22. Flowchart of QSPI Slave Operation (Part 1)

QSPI SLV2 FLOW6

**Figure 15-23. Flowchart of QSPI Slave Operation (Part 2)**

Normally, the SPI bus performs synchronous bidirectional transfers. The serial clock on the SPI bus master supplies the clock signal SCK to time the transfer of data. Four possible combinations of clock phase and polarity can be specified by the CPHA and CPOL bits in SPCR0.

Data is transferred with the most significant bit first. The number of bits transferred per command defaults to eight, but can be set to any value from eight to sixteen bits by writing a value into the BITS field in SPCR0 and setting BITSE in command RAM.

Typically, SPI bus outputs are not open drain unless multiple SPI masters are in the system. If needed, the WOMQ bit in SPCR0 can be set to provide wired-OR, open drain outputs. An external pull-up resistor should be used on each output line. WOMQ affects all QSPI pins regardless of whether they are assigned to the QSPI or used as general-purpose I/O.

## 15.6.5 Master Mode Operation

Setting the MSTR bit in SPCR0 selects master mode operation. In master mode, the QSPI can initiate serial transfers, but cannot respond to externally initiated transfers. When the slave select input of a device configured for master mode is asserted, a mode fault occurs.

Before QSPI operation begins, PQSPAR must be written to assign the necessary pins to the QSPI. The pins necessary for master mode operation are MISO, MOSI, SCK, and one or more of the chip-select pins. MISO is used for serial data input in master mode, and MOSI is used for serial data output. Either or both may be necessary, depending on the particular application. SCK is the serial clock output in master mode and must be assigned to the QSPI for proper operation.

The PORTQS data register must next be written with values that make the QGPIO6/SCK (bit 13 QDSCK of PORTQS) and QGPIO[3:0]/PCS[3:0] (bits 12:9 QDPCS[3:0] of PORTQS) outputs inactive when the QSPI completes a series of transfers. Pins allocated to the QSPI by PQSPAR are controlled by PORTQS when the QSPI is inactive. PORTQS I/O pins driven to states opposite those of the inactive QSPI signals can generate glitches that momentarily enable or partially clock a slave device.

For example, if a slave device operates with an inactive SCK state of logic one (CPOL = 1) and uses active low peripheral chip-select PCS0, the QDSCK and QDPCS0 bits in PORTQS must be set to 0b11. If QDSCK and QDPCS0 = 0b00, falling edges will appear on QGPIO6/SCK and GPIO0/PCS0 as the QSPI relinquishes control of these pins and PORTQS drives them to logic zero from the inactive SCK and PCS0 states of logic one.

Before master mode operation is initiated, QSMCM register DDRQS is written last to direct the data flow on the QSPI pins used. Configure the SCK, MOSI and appropriate chip-select pins PCS[3:0] as outputs. The MISO pin must be configured as an input.

After pins are assigned and configured, write appropriate data to the command queue. If data is to be transmitted, write the data to transmit RAM. Initialize the queue pointers as appropriate.

QSPI operation is initiated by setting the SPE bit in SPCR1. Shortly after SPE is set, the QSPI executes the command at the command RAM address pointed to by NEWQP. Data at the pointer address in transmit RAM is loaded into the data serializer and transmitted. Data that is simultaneously received is stored at the pointer address in receive RAM.

When the proper number of bits have been transferred, the QSPI stores the working queue pointer value in CPTQP, increments the working queue pointer, and loads the next data for transfer from transmit RAM. The command pointed to by the incremented working queue pointer is executed next, unless a new value has been written to NEWQP. If a new queue pointer value is written while a transfer is in progress, that transfer is completed normally.

When the CONT bit in a command RAM byte is set, PCS pins are continuously driven to specified states during and between transfers. If the chip-select pattern changes during or between transfers, the original pattern is driven until execution of the following transfer begins. When CONT is cleared, the data in register PORTQS is driven between transfers. The data in PORTQS must match the inactive states of SCK and any peripheral chip-selects used.

When the QSPI reaches the end of the queue, it sets the SPIF flag. If the SPIFIE bit in SPCR2 is set, an interrupt request is generated when SPIF is asserted. At this point, the QSPI clears SPE and stops unless wraparound mode is enabled.

### 15.6.5.1 Clock Phase and Polarity

In master mode, data transfer is synchronized with the internally-generated serial clock SCK. Control bits, CPHA and CPOL, in SPCR0, control clock phase and polarity. Combinations of CPHA and CPOL determine upon which SCK edge to drive outgoing data from the MOSI pin and to latch incoming data from the MISO pin.

### 15.6.5.2 Baud Rate Selection

Baud rate is selected by writing a value from two to 255 into the SPBR field in SPCR0. The QSPI uses a modulus counter to derive the SCK baud rate from the MCU IMB3 clock.

The following expressions apply to the SCK baud rate:

$$\text{SCK Baud Rate} = \frac{f_{\text{SYS}}}{2 \times \text{SPBR}} \quad \text{Eqn. 15-1}$$

or

$$\text{SPBR} = \frac{f_{\text{SYS}}}{2 \times \text{SCK Baud Rate Desired}} \quad \text{Eqn. 15-2}$$

Giving SPBR a value of zero or one disables the baud rate generator. SCK is disabled and assumes its inactive state. At reset, the SCK baud rate is initialized to one eighth of the IMB3 clock frequency.

Table 15-21 provides some example SCK baud rates with a 40-MHz IMB3 clock.

**Table 15-21. Example SCK Frequencies with a 40-MHz IMB3 Clock**

| Division Ratio | SPBR Value | SCK Frequency |
|----------------|------------|---------------|
| 4              | 2          | 10.00 MHz     |
| 6              | 3          | 6.67 MHz      |
| 8              | 4          | 5.00 MHz      |

**Table 15-21. Example SCK Frequencies with a 40-MHz IMB3 Clock (continued)**

| Division Ratio | SPBR Value | SCK Frequency |
|----------------|------------|---------------|
| 14             | 7          | 2.86 MHz      |
| 28             | 14         | 1.43 MHz      |
| 58             | 29         | 689 kHz       |
| 280            | 140        | 143 kHz       |
| 510            | 255        | 78.43 kHz     |

### 15.6.5.3 Delay Before Transfer

The DSCK bit in each command RAM byte inserts either a standard (DSCK = 0) or user-specified (DSCK = 1) delay from chip-select assertion until the leading edge of the serial clock. The DSCKL field in SPCR1 determines the length of the user-defined delay before the assertion of SCK. The following expression determines the actual delay before SCK when DSCKL is in the range of 1–127:

$$\text{PCS to SCK Delay} = \frac{\text{DSCKL}}{f_{\text{SYS}}} \quad \text{Eqn. 15-3}$$

#### NOTE

A zero value for DSCKL causes a delay of 128 IMB3 clocks, which equals 3.2 μs for a 40-MHz IMB3 clock. Because of design limits, a DSCKL value of one defaults to the same timing as a value of two.

When DSCK equals zero, DSCKL is not used. Instead, the PCS valid-to-SCK transition is one-half the SCK period.

### 15.6.5.4 Delay After Transfer

Delay after transfer can be used to provide a peripheral deselect interval. A delay can also be inserted between consecutive transfers to allow serial A/D converters to complete conversion. Writing a value to the DTL field in SPCR1 specifies a delay period. The DT bit in each command RAM byte determines whether the standard delay period (DT = 0) or the specified delay period (DT = 1) is used. The following expression is used to calculate the delay:

$$\text{Delay after Transfer} = \frac{32 \times \text{DTL}}{f_{\text{SYS}}}$$

where DTL is in the range from one to 255.

A zero value for DTL causes a delay-after-transfer value of 8192 ÷ IMB3 clock frequency (204.8 μs with a 40-MHz IMB3 clock).

If DT is zero in a command RAM byte, a standard delay is inserted.

$$\text{Standard Delay after Transfer} = \frac{17}{f_{\text{SYS}}}$$

Delay after transfer can be used to provide a peripheral deselect interval. A delay can also be inserted between consecutive transfers to allow serial A/D converters to complete conversion.

Adequate delay between transfers must be specified for long data streams because the QSPI requires time to load a transmit RAM entry for transfer. Receiving devices need at least the standard delay between successive transfers. If the IMB3 clock is operating at a slower rate, the delay between transfers must be increased proportionately.

### 15.6.5.5 Transfer Length

There are two transfer length options. The user can choose a default value of eight bits, or a programmed value from eight (0b1000) to 16 (0b0000) bits, inclusive. Reserved values (from 0b0001 to 0b0111) default to eight bits. The programmed value must be written into the BITS field in SPCR0. The BITSE bit in each command RAM byte determines whether the default value (BITSE = 0) or the BITS value (BITSE = 1) is used.

### 15.6.5.6 Peripheral Chip Selects

Peripheral chip-select signals are used to select an external device for serial data transfer. Chip-select signals are asserted when a command in the queue is executed. Signals are asserted at a logic level corresponding to the value of the PCS[3:0] bits in each command byte. More than one chip-select signal can be asserted at a time, and more than one external device can be connected to the PCS pins, provided proper fanout is observed. PCS0 shares a pin with the slave select  $\overline{SS}$  signal, which initiates slave mode serial transfer. If  $\overline{SS}$  is taken low when the QSPI is in master mode, a mode fault occurs.

To configure a peripheral chip select, set the appropriate bit in the PQSPAR, then configure the chip-select pin as an output by setting the appropriate bit in DDRQS. The value of the bit in PORTQS that corresponds to the chip-select pin determines the base state of the chip-select signal. If the base state is zero, chip-select assertion must be active high (PCS bit in command RAM must be set); if base state is one, assertion must be active low (PCS bit in command RAM must be cleared). PORTQS bits are cleared during reset. If no new data is written to PORTQS before pin assignment and configuration as an output, the base state of chip-select signals is zero and chip-select pins are configured for active-high operation.

### 15.6.5.7 Optional Enhanced Peripheral Chip Selects

The MPC561/MPC563 have an optional on-chip decoder for the peripheral chip selects. It is enabled if any of the PCS[4:7]EN bits are enabled in the PDMCR2 register (see [Table 2-6](#)). The decode translates the normal PCS[0:3] chip selects into a 1 of 8 decode. The polarity of the new PCS outputs can be selected by the state of the PCSV bit in the PDMCR2. See [Table 15-22](#).

**Table 15-22. PCS Enhanced Functionality**

| PCS_IN[3:0] | PCS_OUT[7:0] IF PCSV = 0 | PCS_OUT[7:0] IF PCSV = 1 |
|-------------|--------------------------|--------------------------|
| 0000        | 00000001                 | 11111110                 |

#### NOTE

PCS\_IN[3:0] is driven from QSMCM module. PCS\_OUT[7:0] will be driven from the pads to the pins. If the bits PCS4EN, PCS5EN, PCS6EN, PCS7EN are negated (logic 0), PCS\_OUT[3:0] will be the same as PCS\_IN[3:0]. The design assumes that if one of these enable bits is set, PCS function is selected in QSMCM module.

### 15.6.5.8 Master Wraparound Mode

Wraparound mode is enabled by setting the WREN bit in SPCR2. The queue can wrap to pointer address 0x0 or to the address pointed to by NEWQP, depending on the state of the WRTO bit in SPCR2.

In wraparound mode, the QSPI cycles through the queue continuously, even while the QSPI is requesting interrupt service. SPE is not cleared when the last command in the queue is executed. New receive data overwrites previously received data in receive RAM. Each time the end of the queue is reached, the SPIF flag is set. SPIF is not automatically reset. If interrupt-driven QSPI service is used, the service routine must clear the SPIF bit to end the current interrupt request. Additional interrupt requests during servicing can be prevented by clearing SPIFIE, but SPIFIE is buffered. Clearing it does not end the current request.

Wraparound mode is exited by clearing the WREN bit or by setting the HALT bit in SPCR3. Exiting wraparound mode by clearing SPE is not recommended, as clearing SPE may abort a serial transfer in progress. The QSPI sets SPIF, clears SPE, and stops the first time it reaches the end of the queue after WREN is cleared. After HALT is set, the QSPI finishes the current transfer, then stops executing commands. After the QSPI stops, SPE can be cleared.

## 15.6.6 Slave Mode

Clearing the MSTR bit in SPCR0 selects slave mode operation. In slave mode, the QSPI is unable to initiate serial transfers. Transfers are initiated by an external SPI bus master. Slave mode is typically used on a multi-master SPI bus. Only one device can be bus master (operate in master mode) at any given time.

Before QSPI operation is initiated, QSMCM register PQSPAR must be written to assign necessary pins to the QSPI. The pins necessary for slave mode operation are MISO, MOSI, SCK, and PCS0/ $\overline{SS}$ . MISO is used for serial data output in slave mode, and MOSI is used for serial data input. Either or both may be necessary, depending on the particular application. SCK is the serial clock input in slave mode and must be assigned to the QSPI for proper operation. Assertion of the active-low slave select signal  $\overline{SS}$  initiates slave mode operation.

Before slave mode operation is initiated, DDRQS must be written to direct data flow on the QSPI pins used. Configure the MOSI, SCK and PCS0/ $\overline{SS}$  pins as inputs. The MISO pin must be configured as an output.

After pins are assigned and configured, write data to be transmitted into transmit RAM. Command RAM is not used in slave mode, and does not need to be initialized. Set the queue pointers, as appropriate.

When SPE is set and MSTR is clear, a low state on the slave select PCS0/ $\overline{SS}$  pin begins slave mode operation at the address indicated by NEWQP. Data that is received is stored at the pointer address in receive RAM. Data is simultaneously loaded into the data serializer from the pointer address in transmit RAM and transmitted. Transfer is synchronized with the externally generated SCK. The CPHA and CPOL bits determine upon which SCK edge to latch incoming data from the MISO pin and to drive outgoing data from the MOSI pin.

Because the command RAM is not used in slave mode, the CONT, BITSE, DT, DSCK, and peripheral chip-select bits have no effect. The PCS0/ $\overline{SS}$  pin is used only as an input.

The SPBR, DT and DSCKL fields in SPCR0 and SPCR1 bits are not used in slave mode. The QSPI drives neither the clock nor the chip-select pins and thus cannot control clock rate or transfer delay.

Because the BITSE option is not available in slave mode, the BITS field in SPCR0 specifies the number of bits to be transferred for all transfers in the queue. When the number of bits designated by BITS[3:0] has been transferred, the QSPI stores the working queue pointer value in CPTQP, increments the working queue pointer, and loads new transmit data from transmit RAM into the data serializer. The working queue pointer address is used the next time PCS0/ $\overline{SS}$  is asserted, unless the RCPW writes to NEWQP first.

The QSPI shifts one bit for each pulse of SCK until the slave select input goes high. If  $\overline{SS}$  goes high before the number of bits specified by the BITS field is transferred, the QSPI resumes operation at the same pointer address the next time  $\overline{SS}$  is asserted. The maximum value that the BITS field can have is 16. If more than 16 bits are transmitted before  $\overline{SS}$  is negated, pointers are incremented and operation continues.

The QSPI transmits as many bits as it receives at each queue address, until the BITS value is reached or  $\overline{SS}$  is negated.  $\overline{SS}$  does not need to go high between transfers as the QSPI transfers data until reaching the end of the queue, whether  $\overline{SS}$  remains low or is toggled between transfers.

When the QSPI reaches the end of the queue, it sets the SPIF flag. If the SPIFIE bit in SPCR2 is set, an interrupt request is generated when SPIF is asserted. At this point, the QSPI clears SPE and stops unless wraparound mode is enabled.

Slave wraparound mode is enabled by setting the WREN bit in SPCR2. The queue can wrap to pointer address 0x0 or to the address pointed to by NEWQP, depending on the state of the WRTO bit in SPCR2. Slave wraparound operation is identical to master wraparound operation.

### 15.6.6.1 Description of Slave Operation

After reset, the QSMCM registers and the QSPI control registers must be initialized as described above. Although the command control segment is not used, the transmit and receive data segments may, depending upon the application, need to be initialized. If meaningful data is to be sent out from the QSPI, the data to the transmit data should be written to the segment before enabling the QSPI.

If SPE is set and MSTR is not set, a low state on the slave select ( $\overline{\text{PCS0/SS}}$ ) pin commences slave mode operation at the address indicated by NEWQP. The QSPI transmits the data found in the transmit data segment at the address indicated by NEWQP, and the QSPI stores received data in the receive data segment at the address indicated by NEWQP. Data is transferred in response to an external slave clock input at the SCK pin.

Because the command control segment is not used, the command control bits and peripheral chip-select codes have no effect in slave mode operation. The QSPI does not drive any of the four peripheral chip-selects as outputs.  $\overline{\text{PCS0/SS}}$  is used as an input.

Although CONT cannot be used in slave mode, a provision is made to enable receipt of more than 16 data bits. While keeping the QSPI selected ( $\overline{\text{PCS0/SS}}$  is held low), the QSPI stores the number of bits, designated by BITS, in the current receive data segment address, increments NEWQP, and continues storing the remaining bits (up to the BITS value) in the next receive data segment address.

As long as  $\overline{\text{PCS0/SS}}$  remains low, the QSPI continues to store the incoming bit stream in sequential receive data segment addresses, until either the value in BITS is reached or the end-of-queue address is used with wraparound mode disabled.

When the end of the queue is reached, the SPIF flag is asserted, optionally causing an interrupt. If wraparound mode is disabled, any additional incoming bits are ignored.

If wraparound mode is enabled, storing continues at either address 0x0 or the address of NEWQP, depending on the WRTO value. When using this capability to receive a long incoming data stream, the proper delay between transfers must be used. The QSPI requires time, approximately 0.425  $\mu\text{s}$  with a 40-MHz IMB3 clock, to prefetch the next transmit RAM entry for the next transfer. Therefore, a baud rate may be selected that provides at least a 0.6- $\mu\text{s}$  delay between successive transfers to ensure no loss of incoming data. If the IMB3 clock is operating at a slower rate, the delay between transfers must be increased proportionately.

Because the BITSE option in the command control segment is no longer available, BITS sets the number of bits to be transferred for all transfers in the queue until the CPU changes the BITS value. As mentioned above, until  $\overline{\text{PCS0/SS}}$  is negated (brought high), the QSPI continues to shift one bit for each pulse of SCK. If  $\overline{\text{PCS0/SS}}$  is negated before the proper number of bits (according to BITS) is received, the next time the

QSPI is selected it resumes storing bits in the same receive-data segment address where it left off. If more than 16 bits are transferred before negating the  $\overline{\text{PCS0/SS}}$ , the QSPI stores the number of bits indicated by BITS in the current receive data segment address, then increments the address and continues storing as described above.

### NOTE

$\overline{\text{PCS0/SS}}$  does not necessarily have to be negated between transfers.

Once the proper number of bits (designated by BITS) are transferred, the QSPI stores the received data in the receive data segment, stores the internal working queue pointer value in CPTQP, increments the internal working queue pointer, and loads the new transmit data from the transmit data segment into the data serializer. The internal working queue pointer address is used the next time  $\overline{\text{PCS0/SS}}$  is asserted, unless the CPU writes to the NEWQP first.

The DT and DSCK command control bits are not used in slave mode. As a slave, the QSPI does not drive the clock line nor the chip-select lines and, therefore, does not generate a delay.

In slave mode, the QSPI shifts out the data in the transmit data segment. The transmit data is loaded into the data serializer (refer to [Figure 15-1](#)) for transmission. When the  $\overline{\text{PCS0/SS}}$  pin is pulled low the MISO pin becomes active and the serializer then shifts the 16 bits of data out in sequence, most significant bit first, as clocked by the incoming SCK signal. The QSPI uses CPHA and CPOL to determine which incoming SCK edge the MOSI pin uses to latch incoming data, and which edge the MISO pin uses to drive the data out.

The QSPI transmits and receives data until reaching the end of the queue (defined as a match with the address in ENDQP), regardless of whether  $\overline{\text{PCS0/SS}}$  remains selected or is toggled between serial transfers. Receiving the proper number of bits causes the received data to be stored. The QSPI always transmits as many bits as it receives at each queue address, until the BITS value is reached or  $\overline{\text{PCS0/SS}}$  is negated.

## 15.6.7 Slave Wraparound Mode

When the QSPI reaches the end of the queue, it always sets the SPIF flag, whether wraparound mode is enabled or disabled. An optional interrupt to the CPU is generated when SPIF is asserted. At this point, the QSPI clears SPE and stops unless wraparound mode is enabled. A description of SPIFIE bit can be found in [15.6.1.3 QSPI Control Register 2 \(SPCR2\)](#).

In wraparound mode, the QSPI cycles through the queue continuously. Each time the end of the queue is reached, the SPIF flag is set. If the CPU fails to clear SPIF, it remains set, and the QSPI continues to send interrupt requests to the CPU (assuming SPIFIE is set). The user may avoid causing CPU interrupts by clearing SPIFIE.

As SPIFIE is buffered, clearing it after the SPIF flag is asserted does not immediately stop the CPU interrupts, but only prevents future interrupts from this source. To clear the current interrupt, the CPU must read QSPI register SPSR with SPIF asserted, followed by a write to SPSR with zero in SPIF (clear SPIF). Execution continues in wraparound mode even while the QSPI is requesting interrupt service from the CPU. The internal working queue pointer is incremented to the next address and the commands are

executed again. SPE is not cleared by the QSPI. New receive data overwrites previously received data located in the receive data segment.

Wraparound mode is properly exited in two ways:

- The CPU may disable wrap-around mode by clearing WREN. The next time end of the queue is reached, the QSPI sets SPIF, clears SPE, and stops.
- The CPU sets HALT. This second method halts the QSPI after the current transfer is completed, allowing the CPU to negate SPE. The CPU can immediately stop the QSPI by clearing SPE; however, this method is not recommended, as it causes the QSPI to abort a serial transfer in process.

### 15.6.8 Mode Fault

MODF is asserted by the QSPI when the QSPI is the serial master (MSTR = 1) and the slave select (PCS0/ $\overline{SS}$ ) input pin is pulled low by an external driver. This is possible only if the PCS0/ $\overline{SS}$  pin is configured as input by QDDR. This low input to  $\overline{SS}$  is not a normal operating condition. It indicates that a multimaster system conflict may exist, that another MCU is requesting to become the SPI network master, or simply that the hardware is incorrectly affecting PCS0/ $\overline{SS}$ . SPE in SPCR1 is cleared, disabling the QSPI. The QSPI pins revert to control by QPDR. If MODF is set and HMIE in SPCR3 is asserted, the QSPI generates an interrupt to the CPU.

The CPU may clear MODF by reading SPSR with MODF asserted, followed by writing SPSR with a zero in MODF. After correcting the mode fault problem, the QSPI can be re-enabled by asserting SPE.

The PCS0/ $\overline{SS}$  pin may be configured as a general-purpose output instead of input to the QSPI. This inhibits the mode fault checking function. In this case, MODF is not used by the QSPI.

## 15.7 Serial Communication Interface

The dual, independent, serial communication interface (DSCI) communicates with external devices through an asynchronous serial bus. The two SCI modules are functionally equivalent, except that the SCI1 also provides 16-deep queue capabilities for the transmit and receive operations. The SCIs are fully compatible with other Freescale SCI systems. The DSCI has all of the capabilities of previous SCI systems as well as several significant new features.

Figure 15-24 is a block diagram of the SCI transmitter. Figure 15-25 is a block diagram of the SCI receiver.

Figure 15-24. SCI Transmitter Block Diagram

Figure 15-25. SCI Receiver Block Diagram

## 15.7.1 SCI Registers

The SCI programming model includes the QSMCM global and pin control registers and the DSCI registers.

The DSCI registers, listed in [Table 15-23](#), consist of five control registers, three status registers, and 34 data registers. All registers may be read or written at any time by the CPU. Rewriting the same value to any DSCI register does not disrupt operation; however, writing a different value into a DSCI register when the DSCI is running may disrupt operation. To change register values, the receiver and transmitter should be disabled with the transmitter allowed to finish first. The status flags in register SCxSR can be cleared at any time.

**Table 15-23. SCI Registers**

\*Reads access the RDRx; writes access the TDRx.

During SCIx initialization, two bits in the SCCxR1 should be written last: the transmitter enable (TE) and receiver enable (RE) bits, which enable SCIx. Registers SCCxR0 and SCCxR1 should both be initialized at the same time or before TE and RE are asserted. A single half-word write to SCCxR1 can be used to initialize SCIx and enable the transmitter and receiver.

### 15.7.2 SCI Control Register 0 (SCCxR0)

SCCxR0 contains the SCIx baud rate selection field and two bits controlling the clock source. The baud rate must be set before the SCI is enabled. The CPU can read and write SCCxR0 at any time.

Changing the value of SCCxR0 bits during a transfer operation can disrupt the transfer. Before changing register values, allow the SCI to complete the current transfer, then disable the receiver and transmitter.

| 3:15 | SCxBR | SCI baud rate. The SCI baud rate is programmed by writing a 13-bit value to this field. Writing a value of zero to SCxBR disables the baud rate generator. Baud clock rate is calculated as follows:<br><br>$\text{SCI Baud Rate} = \frac{f_{\text{SYS}}}{32 \times \text{SCxBR}}$ where SCxBR is in the range of 1 to 8191.<br>Refer to Section 15.7.7.3, “Baud Clock,” for more information. |

### 15.7.3 SCI Control Register 1 (SCCxR1)

SCCxR1 contains SCIx configuration parameters, including transmitter and receiver enable bits, interrupt enable bits, and operating mode enable bits. The CPU can read or write this register at any time. The SCI can modify the RWU bit under certain circumstances.

Changing the value of SCCxR1 bits during a transfer operation can disrupt the transfer. Before changing register values, allow the SCI to complete the current transfer, then disable the receiver and transmitter.

## 15.7.4 SCI Status Register (SCxSR)

SCxSR contains flags that show SCI operating conditions. These flags are cleared either by SCIx hardware or by a read/write sequence. The sequence consists of reading the SCxSR (either the upper byte, lower byte, or the entire half-word) with a flag bit set, then reading (or writing, in the case of flags TDRE and TC) the SCxDR (either the lower byte or the half-word).

The contents of the two 16-bit registers SCxSR and SCxDR appear as upper and lower half-words, respectively, when the SCxSR is read into a 32-bit register. An upper byte access of SCxSR is meaningful only for reads. Note that a word read can simultaneously access both registers SCxSR and SCxDR. This action clears the receive status flag bits that were set at the time of the read, but does not clear the TDRE or TC flags. To clear TC, the SCxSR read must be followed by a write to register SCxDR (either the lower byte or the half-word). The TDRE flag in the status register is read-only.

If an internal SCI signal for setting a status bit comes after the CPU has read the asserted status bits but before the CPU has read or written the SCxDR, the newly set status bit is not cleared. Instead, SCxSR must be read again with the bit set and SCxDR must be read or written before the status bit is cleared.

### NOTE

None of the status bits are cleared by reading a status bit while it is set and then writing zero to that same bit. Instead, the procedure outlined above must be followed. Note further that reading either byte of SCxSR causes all 16 bits to be accessed, and any status bits already set in either byte are armed to clear on a subsequent read or write of SCxDR.

| 7    | TDRE | Transmit data register empty. TDRE is set when the byte in TDRx is transferred to the transmit serial shifter. If this bit is zero, the transfer is yet to occur and a write to TDRx will overwrite the previous value. New data is not transmitted if TDRx is written without first clearing TDRE.<br>0 Transmit data register still contains data to be sent to the transmit serial shifter.<br>1 A new character can now be written to the transmit data register.<br>For transmit queue operation, this bit should be ignored by software.                                                                                                                                                                                                                                                                                                                        |
| 8    | TC   | Transmit complete. TC is set when the transmitter finishes shifting out all data, queued preambles (mark/idle-line), or queued breaks (logic zero).<br>0 SCI transmitter is busy.<br>1 SCI transmitter is idle.<br>For transmit queue operation, TC is cleared when SCxSR is read with TC set, followed by a write to SCTQ[0:15].                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 9    | RDRF | Receive data register full. RDRF is set when the contents of the receive serial shifter are transferred to register RDRx. If one or more errors are detected in the received word, the appropriate flag(s) (NF, FE, or PF) are set within the same clock cycle.<br>0 Receive data register is empty or contains previously read data.<br>1 Receive data register contains new data.<br>For receiver queue operation, this bit should be ignored by software.                                                                                                                                                                                                                                                                                                                                                                                                          |
| 10   | RAF  | Receiver active flag. RAF indicates whether the receiver is busy. This flag is set when the receiver detects a possible start bit and is cleared when the chosen type of idle line is detected. RAF can be used to reduce collisions in systems with multiple masters.<br>0 SCI receiver is idle.<br>1 SCI receiver is busy.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| 11   | IDLE | Idle line detected. IDLE is set when the receiver detects an idle-line condition (reception of a minimum of 10 or 11 consecutive ones as specified by ILT in SCCxR1). This bit is not set by the idle-line condition when RWU in SCCxR1 is set. Once cleared, IDLE is not set again until after RDRF is set (after the line is active and becomes idle again). If a break is received, RDRF is set, allowing a subsequent idle line to be detected again.<br>Under certain conditions, the IDLE flag may be set immediately following the negation of RE in SCCxR1. System designs should ensure this causes no detrimental effects.<br>0 SCI receiver did not detect an idle-line condition.<br>1 SCI receiver detected an idle-line condition.<br>For receiver queue operation, IDLE is cleared when SCxSR is read with IDLE set, followed by a read of SCRQ[0:15]. |

**Table 15-26. SCxSR Bit Descriptions (continued)**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 12   | OR   | <p>Overrun error. OR is set when a new byte is ready to be transferred from the receive serial shifter to register RDRx, and RDRx is already full (RDRF is still set). Data transfer is inhibited until OR is cleared. Previous data in RDRx remains valid, but additional data received during an overrun condition (including the byte that set OR) is lost.</p> <p>Note that whereas the other receiver status flags (NF, FE, and PF) reflect the status of data already transferred to RDRx, the OR flag reflects an operational condition that resulted in a loss of data to RDRx.</p> <p>0 RDRF is cleared before new data arrives.<br/>1 RDRF is not cleared before new data arrives.</p>                                                                                                                     |
| 13   | NF   | <p>Noise error flag. NF is set when the receiver detects noise on a valid start bit, on any of the data bits, or on the stop bit(s). It is not set by noise on the idle line or on invalid start bits. Each bit is sampled three times for noise. If the three samples are not at the same logic level, the majority value is used for the received data value, and NF is set. NF is not set until the entire frame is received and RDRF is set.</p> <p>Although no interrupt is explicitly associated with NF, an interrupt can be generated with RDRF, and the interrupt handler can check NF.</p> <p>0 No noise detected in the received data.<br/>1 Noise detected in the received data.</p> <p>For receiver queue operation NF is cleared when SCxSR is read with NF set, followed by a read of SCRQ[0:15].</p> |
| 14   | FE   | <p>Framing error. FE is set when the receiver detects a zero where a stop bit (one) was expected. A framing error results when the frame boundaries in the received bit stream are not synchronized with the receiver bit counter. FE is not set until the entire frame is received and RDRF is set.</p> <p>Although no interrupt is explicitly associated with FE, an interrupt can be generated with RDRF, and the interrupt handler can check FE.</p> <p>0 No framing error detected in the received data.<br/>1 Framing error or break detected in the received data.</p>                                                                                                                                                                                                                                        |
| 15   | PF   | <p>Parity error. PF is set when the receiver detects a parity error. PF is not set until the entire frame is received and RDRF is set.</p> <p>Although no interrupt is explicitly associated with PF, an interrupt can be generated with RDRF, and the interrupt handler can check PF.</p> <p>0 No parity error detected in the received data.<br/>1 Parity error detected in the received data.</p>                                                                                                                                                                                                                                                                                                                                                                                                                 |

### 15.7.5 SCI Data Register (SCxDR)

The SCxDR consists of two data registers located at the same address. The receive data register (RDRx) is a read-only register that contains data received by the SCI serial interface. Data is shifted into the receive serial shifter and is transferred to RDRx. The transmit data register (TDRx) is a write-only register that contains data to be transmitted. Data is first written to TDRx, then transferred to the transmit serial shifter, where additional format bits are added before transmission.

Figure 15-29. SCI Data Register (SCxDR)

Table 15-27. SCxDR Bit Descriptions

| Bits | Name              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|------|-------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:6  | —                 | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 7:15 | R[8:0]/<br>T[8:0] | R[7:0]/T[7:0] contain either the eight data bits received when SCxDR is read, or the eight data bits to be transmitted when SCxDR is written. R8/T8 are used when the SCI is configured for nine-bit operation (M = 1). When the SCI is configured for 8-bit operation, R8/T8 have no meaning or effect.<br>Accesses to the lower byte of SCxDR triggers the mechanism for clearing the status bits or for initiating transmissions whether byte, half-word, or word accesses are used. |

### 15.7.6 SCI Pins

The RXD1 and RXD2 pins are the receive data pins for the SCI1 and SCI2, respectively. TXD1 and TXD2 are the transmit data pins for the two SCI modules. The pins and their functions are listed in [Table 15-28](#).

Table 15-28. SCI Pin Functions

| Pin Names     | Mnemonic   | Mode                                        | Function                                              |
|---------------|------------|---------------------------------------------|-------------------------------------------------------|
| Receive Data  | RXD1, RXD2 | Receiver disabled<br>Receiver enabled       | General purpose input<br>Serial data input to SCI     |
| Transmit Data | TXD1, TXD2 | Transmitter disabled<br>Transmitter enabled | General purpose output<br>Serial data output from SCI |

### 15.7.7 SCI Operation

The SCI can operate in polled or interrupt-driven mode. Status flags in SCxSR reflect SCI conditions regardless of the operating mode chosen. The TIE, TCIE, RIE, and ILIE bits in SCCxR1 enable interrupts for the conditions indicated by the TDRE, TC, RDRE, and IDLE bits in SCxSR, respectively.

#### 15.7.7.1 Definition of Terms

|           |                                                                                                                                                                                                    |
|-----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Bit-time  | The time required to transmit or receive one bit of data, which is equal to one cycle of the baud frequency.                                                                                       |
| Start bit | One bit-time of logic zero that indicates the beginning of a data frame. A start bit must begin with a one-to-zero transition and be preceded by at least three receive time samples of logic one. |
| Stop bit  | One bit-time of logic one that indicates the end of a data frame.                                                                                                                                  |

|             |                                                                                         |
|-------------|-----------------------------------------------------------------------------------------|
| Frame       | A complete unit of serial information. The SCI can use 10-bit or 11-bit frames.         |
| Data frame  | A start bit, a specified number of data or information bits, and at least one stop bit. |
| Idle frame  | A frame that consists of consecutive ones. An idle frame has no start bit.              |
| Break frame | A frame that consists of consecutive zeros. A break frame has no stop bits.             |

### 15.7.7.2 Serial Formats

All data frames must have a start bit and at least one stop bit. Receiving and transmitting devices must use the same data frame format. The SCI provides hardware support for both 10-bit and 11-bit frames. The M bit in SCCxR1 specifies the number of bits per frame.

The most common data frame format for NRZ (non-return to zero) serial interfaces is one start bit, eight data bits (Lsb first), and one stop bit (ten bits total). The most common 11-bit data frame contains one start bit, eight data bits, a parity or control bit, and one stop bit. Ten-bit and 11-bit frames are shown in [Table 15-29](#).

**Table 15-29. Serial Frame Formats**

| 10-bit Frames |      |                |                | SCCxR1 Bits |    |
|---------------|------|----------------|----------------|-------------|----|
| Start         | Data | Parity/Control | STOP           | M           | PE |
| 1             | 7    | —              | 2              | 0           | 0  |
| 1             | 7    | 1              | 1              | 0           | 1  |
| 1             | 8    | —              | 1              | 0           | 0  |
| 11-Bit Frames |      |                |                | SCCxR1 Bits |    |
| Start         | Data | Parity/Control | STOP           | M           | PE |
| 1             | 8    | —              | 2 <sup>1</sup> | 1           | 1  |
| 1             | 8    | 1              | 1              | 1           | 1  |
| 1             | 9    | —              | 1              | 1           | 0  |

<sup>1</sup> The MSB data bit can also serve as a second STOP bit. By setting this bit permanently to one, communication with other SCIs requiring two STOP bits could be accommodated.

### 15.7.7.3 Baud Clock

The SCI baud rate is programmed by writing a 13-bit value to the SCxBR field in SCI control register zero (SCCxR0). The baud rate is derived from the MCU IMB3 clock by a modulus counter. Writing a value of zero to SCxBR[12:0] disables the baud rate generator. The baud rate is calculated as follows:

$$\text{SCI Baud Rate} = \frac{f_{\text{SYS}}}{32 \times \text{SCxBR}}$$

or **Eqn. 15-4**

$$\text{SCxBR} = \frac{f_{\text{SYS}}}{32 \times \text{SCI Baud Rate Desired}}$$

where SCxBR is in the range {1, 2, 3, ..., 8191}.

The SCI receiver operates asynchronously. An internal clock is necessary to synchronize with an incoming data stream. The SCI baud rate generator produces a receive time sampling clock with a frequency 16 times that of the SCI baud rate. The SCI determines the position of bit boundaries from transitions within the received waveform, and adjusts sampling points to the proper positions within the bit period.

Table 15-30 shows possible baud rates for a 40-MHz IMB3 clock. The maximum baud rate with this IMB3 clock speed is 1250 Kbaud.

**Table 15-30. Examples of SCIx Baud Rates<sup>1</sup>**

| Nominal Baud Rate | Actual Baud Rate | Percent Error | Value of SCxBR |
|-------------------|------------------|---------------|----------------|
| 1,250,000.00      | 1,250,000.00     | 0.00          | 1              |
| 57,600.00         | 56,818.18        | -1.36         | 22             |
| 38,400.00         | 37,878.79        | -1.36         | 33             |
| 32,768.00         | 32,894.74        | 0.39          | 38             |
| 28,800.00         | 29,069.77        | 0.94          | 43             |
| 19,200.00         | 19,230.77        | 0.16          | 65             |
| 14,400.00         | 14,367.81        | -0.22         | 87             |
| 9,600.00          | 9,615.38         | 0.16          | 130            |
| 4,800.00          | 4,807.69         | 0.16          | 260            |
| 2,400.00          | 2,399.23         | -0.03         | 521            |
| 1,200.00          | 1,199.62         | -0.03         | 1042           |
| 600.00            | 600.09           | 0.02          | 2083           |
| 300.00            | 299.98           | -0.01         | 4167           |

<sup>1</sup>These rates are based on a 40-MHz IMB3 clock.

#### 15.7.7.4 Parity Checking

The PT bit in SCCxR1 selects either even (PT = 0) or odd (PT = 1) parity. PT affects received and transmitted data. The PE bit in SCCxR1 determines whether parity checking is enabled (PE = 1) or disabled (PE = 0). When PE is set, the MSB of data in a frame (i.e., the bit preceding the stop bit) is used for the parity function. For transmitted data, a parity bit is generated. For received data, the parity bit is checked. When parity checking is enabled, the PF bit in the SCI status register (SCxSR) is set if a parity error is detected.

Enabling parity affects the number of data bits in a frame, which can in turn affect frame size. Table 15-31 shows possible data and parity formats.

**Table 15-31. Effect of Parity Checking on Data Size**

| M | PE | Result                    |
|---|----|---------------------------|
| 0 | 0  | 8 data bits               |
| 0 | 1  | 7 data bits, 1 parity bit |

**Table 15-31. Effect of Parity Checking on Data Size**

| M | PE | Result                    |
|---|----|---------------------------|
| 1 | 0  | 9 data bits               |
| 1 | 1  | 8 data bits, 1 parity bit |

### 15.7.7.5 Transmitter Operation

The transmitter consists of a serial shifter and a parallel data register (TDRx) located in the SCI data register (SCxDR). The serial shifter cannot be directly accessed by the CPU. The transmitter is double-buffered, which means that data can be loaded into the TDRx while other data is shifted out. The TE bit in SCCxR1 enables (TE = 1) and disables (TE = 0) the transmitter.

The shifter output is connected to the TXD pin while the transmitter is operating (TE = 1, or TE = 0 and transmission in progress). Wired-OR operation should be specified when more than one transmitter is used on the same SCI bus. The WOMS bit in SCCxR1 determines whether TXD is an open drain (wired-OR) output or a normal CMOS output. An external pull-up resistor on TXD is necessary for wired-OR operation. WOMS controls TXD function, regardless of whether the pin is used by the SCI or as a general-purpose output pin.

Data to be transmitted is written to SCxDR, then transferred to the serial shifter. Before writing to TDRx, the transmit data register empty (TDRE) flag in SCxSR should be checked. When TDRE = 0, the TDRx contains data that has not been transferred to the shifter. Writing to SCxDR again overwrites the data. If TDRE = 1, then TDRx is empty, and new data may be written to TDRx, clearing TDRE.

As soon as the data in the transmit serial shifter has shifted out and if a new data frame is in TDRx (TDRE = 0), then the new data is transferred from TDRx to the transmit serial shifter and TDRE is set automatically. An interrupt may optionally be generated at this point.

The transmission complete (TC) flag in SCxSR shows transmitter shifter state. When TC = 0, the shifter is busy. TC is set when all shifting operations are completed. TC is not automatically cleared. The processor must clear it by first reading SCxSR while TC is set, then writing new data to SCxDR, or writing to SCTQ[0:15] for transmit queue operation.

The state of the serial shifter is checked when the TE bit is set. If TC = 1, an idle frame is transmitted as a preamble to the following data frame. If TC = 0, the current operation continues until the final bit in the frame is sent, then the preamble is transmitted. The TC bit is set at the end of preamble transmission.

The SBK bit in SCCxR1 is used to insert break frames in a transmission. A non-zero integer number of break frames are transmitted while SBK is set. Break transmission begins when SBK is set, and ends with the transmission in progress at the time either SBK or TE is cleared. If SBK is set while a transmission is in progress, that transmission finishes normally before the break begins. To ensure the minimum break time, toggle SBK quickly to one and back to zero. The TC bit is set at the end of break transmission. After break transmission, at least one bit-time of logic level one (mark idle) is transmitted to ensure that a subsequent start bit can be detected.

If TE remains set, after all pending idle, data and break frames are shifted out, TDRE and TC are set and TXD is held at logic level one (mark).

When TE is cleared, the transmitter is disabled after all pending idle, data, and break frames are transmitted. The TC flag is set, and control of the TXD pin reverts to PQSPAR and DDRQS. Buffered data is not transmitted after TE is cleared. To avoid losing data in the buffer, do not clear TE until TDRE is set.

Some serial communication systems require a mark on the TXD pin even when the transmitter is disabled. Configure the TXD pin as an output, then write a one to either QDTX1 or QDTX2 of the PORTQS register. See [Section 15.5.1, “Port QS Data Register \(PORTQS\)”](#). When the transmitter releases control of the TXD pin, it reverts to driving a logic one output.

To insert a delimiter between two messages, to place non-listening receivers in wake-up mode between transmissions, or to signal a re-transmission by forcing an idle-line, clear and then set TE before data in the serial shifter has shifted out. The transmitter finishes the transmission, then sends a preamble. After the preamble is transmitted, if TDRE is set, the transmitter marks idle. Otherwise, normal transmission of the next sequence begins.

Both TDRE and TC have associated interrupts. The interrupts are enabled by the transmit interrupt enable (TIE) and transmission complete interrupt enable (TCIE) bits in SCCxR1. Service routines can load the last data frame in a sequence into SCxDR, then terminate the transmission when a TDRE interrupt occurs.

Two SCI messages can be separated with minimum idle time by using a preamble of 10 bit-times (11 if a 9-bit data format is specified) of marks (logic ones). Follow these steps:

1. Write the last data frame of the first message to the TDRx
2. Wait for TDRE to go high, indicating that the last data frame is transferred to the transmit serial shifter
3. Clear TE and then set TE back to one. This queues the preamble to follow the stop bit of the current transmission immediately.
4. Write the first data frame of the second message to register TDRx

In this sequence, if the first data frame of the second message is not transferred to TDRx prior to the finish of the preamble transmission, then the transmit data line (TXDx pin) marks idle (logic one) until TDRx is written. In addition, if the last data frame of the first message finishes shifting out (including the stop bit) and TE is clear, TC goes high and transmission is considered complete. The TXDx pin reverts to being a general-purpose output pin.

### 15.7.7.6 Receiver Operation

The receiver can be divided into two segments. The first is the receiver bit processor logic that synchronizes to the asynchronous receive data and evaluates the logic sense of each bit in the serial stream. The second receiver segment controls the functional operation and the interface to the CPU including the conversion of the serial data stream to parallel access by the CPU.

#### 15.7.7.7 Receiver Bit Processor

The receiver bit processor contains logic to synchronize the bit-time of the incoming data and to evaluate the logic sense of each bit. To accomplish this an RT clock, which is 16 times the baud rate, is used to sample each bit. Each bit-time can thus be divided into 16 time periods called RT1–RT16. The receiver

looks for a possible start bit by watching for a high-to-low transition on the RXDx pin and by assigning the RT time labels appropriately.

When the receiver is enabled by writing RE in SCCxR1 to one, the receiver bit processor logic begins an asynchronous search for a start bit. The goal of this search is to gain synchronization with a frame. The bit-time synchronization is done at the beginning of each frame so that small differences in the baud rate of the receiver and transmitter are not cumulative. SCIx also synchronizes on all one-to-zero transitions in the serial data stream, which makes SCIx tolerant to small frequency variations in the received data stream.

The sequence of events used by the receiver to find a start bit is listed below.

1. Sample RXDx input during each RT period and maintain these samples in a serial pipeline that is three RT periods deep.
2. If RXDx is low during this RT period, go to step 1.
3. If RXDx is high during this RT period, store sample and proceed to step 4.
4. If RXDx is low during this RT period, but not high for the previous three RT periods (which is noise only), set an internal working noise flag and go to step 1, since this transition was not a valid start bit transition.
5. If RXDx is low during this RT period and has been high for the previous three RT periods, call this period RT1, set RAF, and proceed to step 6.
6. Skip RT2 but place RT3 in the pipeline and proceed to step 7.
7. Skip RT4 and sample RT5. If both RT3 and RT5 are high (RT1 was noise only), set an internal working noise flag. Go to step 3 and clear RAF. Otherwise, place RT5 in the pipeline and proceed to step 8.
8. Skip RT6 and sample RT7. If any two of RT3, RT5, or RT7 is high (RT1 was noise only), set an internal working noise flag. Go to step 3 and clear RAF. Otherwise, place RT7 in the pipeline and proceed to step 9.
9. A valid start bit is found and synchronization is achieved. From this point on until the end of the frame, the RT clock will increment starting over again with RT1 on each one-to-zero transition or each RT16. The beginning of a bit-time is thus defined as RT1 and the end of a bit-time as RT16.

Upon detection of a valid start bit, synchronization is established and is maintained through the reception of the last stop bit, after which the procedure starts all over again to search for a new valid start bit. During a frame's reception, SCIx resynchronizes the RT clock on any one-to-zero transitions.

Additional logic in the receiver bit processor determines the logic level of the received bit and implements an advanced noise-detection function. During each bit-time of a frame (including the start and stop bits), three logic-sense samples are taken at RT8, RT9, and RT10. The logic sense of the bit-time is decided by a majority vote of these three samples. This logic level is shifted into register RDRx for every bit except the start and stop bits.

If RT8, RT9, and RT10 do not all agree, an internal working noise flag is set. Additionally for the start bit, if RT3, RT5, and RT7 do not all agree, the internal working noise flag is set. If this flag is set for any of the bit-times in a frame, the NF flag in SCxSR is set concurrently with the RDRF flag in SCxSR when the data is transferred to register RDRx. The user must determine if the data received with NF set is valid. Noise on the RXDx pin does not necessarily corrupt all data.

\* Restart RT Clock

**Figure 15-30. Start Search Example**

The RE bit in SCCxR1 enables (RE = 1) and disables (RE = 0) the receiver. The receiver contains a receive serial shifter and a parallel receive data register (RDRx) located in the SCI data register (SCxDR). The serial shifter cannot be directly accessed by the CPU. The receiver is double-buffered, allowing data to be held in the RDRx while other data is shifted in.

Receiver bit processor logic drives a state machine that determines the logic level for each bit-time. This state machine controls when the bit processor logic is to sample the RXD pin and also controls when data is to be passed to the receive serial shifter. A receive time clock is used to control sampling and synchronization. Data is shifted into the receive serial shifter according to the most recent synchronization of the receive time clock with the incoming data stream. From this point on, data movement is synchronized with the MCU IMB3 clock. Operation of the receiver state machine is detailed in the *Queued Serial Module Reference Manual*.

The number of bits shifted in by the receiver depends on the serial format. However, all frames must end with at least one stop bit. When the stop bit is received, the frame is considered to be complete, and the received data in the serial shifter is transferred to the RDRx. The receiver data register flag (RDRF) is set when the data is transferred.

The stop bit is always a logic one. If a logic zero is sensed during this bit-time, the FE flag in SCxSR is set. A framing error is usually caused by mismatched baud rates between the receiver and transmitter or by a significant burst of noise. Note that a framing error is not always detected; the data in the expected stop bit-time may happen to be a logic one.

Noise errors, parity errors, and framing errors can be detected while a data stream is being received. Although error conditions are detected as bits are received, the noise flag (NF), the parity flag (PF), and the framing error (FE) flag in SCxSR are not set until data is transferred from the serial shifter to the RDRx.

RDRF must be cleared before the next transfer from the shifter can take place. If RDRF is set when the shifter is full, transfers are inhibited and the overrun error (OR) flag in SCxSR is set. OR indicates that the RDRx needs to be serviced faster. When OR is set, the data in the RDRx is preserved, but the data in the serial shifter is lost.

When a completed frame is received into the RDRx, either the RDRF or OR flag is always set. If RIE in SCCxR1 is set, an interrupt results whenever RDRF is set. The receiver status flags NF, FE, and PF are set simultaneously with RDRF, as appropriate. These receiver flags are never set with OR because the flags apply only to the data in the receive serial shifter. The receiver status flags do not have separate interrupt enables, since they are set simultaneously with RDRF and must be read at the same time as RDRF.

When the CPU reads SCxSR and SCxDR in sequence, it acquires status and data, and also clears the status flags. Reading SCxSR acquires status and arms the clearing mechanism. Reading SCxDR acquires data and clears SCxSR.

### 15.7.7.9 Idle-Line Detection

During a typical serial transmission, frames are transmitted isochronically and no idle time occurs between frames. Even when all the data bits in a frame are logic ones, the start bit provides one logic zero bit-time during the frame. An idle line is a sequence of contiguous ones equal to the current frame size. Frame size is determined by the state of the M bit in SCCxR1.

The SCI receiver has both short and long idle-line detection capability. Idle-line detection is always enabled. The idle-line type (ILT) bit in SCCxR1 determines which type of detection is used. When an idle-line condition is detected, the IDLE flag in SCxSR is set.

For short idle-line detection, the receiver bit processor counts contiguous logic one bit-times whenever they occur. Short detection provides the earliest possible recognition of an idle-line condition, because the stop bit and contiguous logic ones before and after it are counted. For long idle-line detection, the receiver counts logic ones after the stop bit is received. Only a complete idle frame causes the IDLE flag to be set.

In some applications, software overhead can cause a bit-time of logic level one to occur between frames. This bit-time does not affect content, but if it occurs after a frame of ones when short detection is enabled, the receiver flags an idle line.

When the ILIE bit in SCCxR1 is set, an interrupt request is generated when the IDLE flag is set. The flag is cleared by reading SCxSR and SCxDR in sequence. For receiver queue operation, IDLE is cleared when SCxSR is read with IDLE set, followed by a read of SCRQ[0:15]. IDLE is not set again until after at least one frame has been received (RDRF = 1). This prevents an extended idle interval from causing more than one interrupt.

### 15.7.7.10 Receiver Wake-Up

The receiver wake-up function allows a transmitting device to direct a transmission to a single receiver or to a group of receivers by sending an address frame at the start of a message. Hardware activates each receiver in a system under certain conditions. Resident software must process address information and enable or disable receiver operation.

A receiver is placed in wake-up mode by setting the RWU bit in SCCxR1. While RWU is set, receiver status flags and interrupts are disabled. Although the software can clear RWU, it is normally cleared by hardware during wake-up.

The WAKE bit in SCCxR1 determines which type of wake-up is used. When WAKE = 0, idle-line wake-up is selected. When WAKE = 1, address-mark wake-up is selected. Both types require a software-based device addressing and recognition scheme.

Idle-line wake-up allows a receiver to sleep until an idle line is detected. When an idle line is detected, the receiver clears RWU and wakes up. The receiver waits for the first frame of the next transmission. The data frame is received normally, transferred to the RDRx, and the RDRF flag is set. If software does not recognize the address, it can set RWU and put the receiver back to sleep. For idle-line wake-up to work, there must be a minimum of one frame of idle line between transmissions. There must be no idle time between frames within a transmission.

Address mark wake-up uses a special frame format to wake up the receiver. When the MSB of an address-mark frame is set, that frame contains address information. The first frame of each transmission must be an address frame. When the MSB of a frame is set, the receiver clears RWU and wakes up. The data frame is received normally, transferred to the RDRx, and the RDRF flag is set. If software does not recognize the address, it can set RWU and put the receiver back to sleep. Address mark wake-up allows idle time between frames and eliminates idle time between transmissions. However, there is a loss of efficiency because of an additional bit-time per frame.

### 15.7.7.11 Internal Loop Mode

The LOOPS bit in SCCxR1 controls a feedback path in the data serial shifter. When LOOPS is set, the SCI transmitter output is fed back into the receive serial shifter. TXD is asserted (idle line). Both transmitter and receiver must be enabled before entering loop mode.

## 15.8 SCI Queue Operation

### 15.8.1 Queue Operation of SCI1 for Transmit and Receive

The SCI1 serial module allows for queueing on transmit and receive data frames. In the standard mode, in which the queue is disabled, the SCI1 operates as previously defined (i.e., transmit and receive operations done via SC1DR). However, if the SCI1 queue feature is enabled (by setting the QTE and/or QRE bits within QSCI1CR) a set of 16 entry queues is allocated for the receive and/or transmit operation. Through software control the queue is capable of continuous receive and transfer operations within the SCI1 serial unit.

### 15.8.2 Queued SCI1 Status and Control Registers

The SCI1 queue uses the following registers:

- QSCI1 control register (QSCI1CR, address offset 0x28)
- QSCI1 status register (QSCI1SR, address offset 0x2A)

### 15.8.2.1 QSCI1 Control Register (QSCI1CR)

**Table 15-32. QSCI1CR Bit Descriptions**

| Bits | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:3  | QTPNT | Queue transmit pointer. QTPNT is a 4-bit counter used to indicate the next data frame within the transmit queue to be loaded into the SC1DR. This feature allows for ease of testability. This field is writable in test mode only; otherwise it is read-only.                                                                                                                                                                                                      |
| 4    | QTHFI | Receiver queue top-half full interrupt. When set, QTHFI enables an SCI1 interrupt whenever the QTHF flag in QSCI1SR is set. The interrupt is blocked by negating QTHFI. This bit refers to the queue locations SCRQ[0:7].<br>0 QTHF interrupt inhibited<br>1 Queue top-half full (QTHF) interrupt enabled                                                                                                                                                           |
| 5    | QBHFI | Receiver queue bottom-half full interrupt. When set, QBHFI enables an SCI1 interrupt whenever the QBHF flag in QSCI1SR is set. The interrupt is blocked by negating QBHFI. This bit refers to the queue locations SCRQ[8:15].<br>0 QBHF interrupt inhibited<br>1 Queue bottom-half full (QBHF) interrupt enabled                                                                                                                                                    |
| 6    | QTHEI | Transmitter queue top-half empty interrupt. When set, QTHEI enables an SCI1 interrupt whenever the QTHE flag in QSCI1SR is set. The interrupt is blocked by negating QTHEI. This bit refers to the queue locations SCTQ[0:7].<br>0 QTHE interrupt inhibited<br>1 Queue top-half empty (QTHE) interrupt enabled                                                                                                                                                      |
| 7    | QBHEI | Transmitter queue bottom-half empty interrupt. When set, QBHEI enables an SCI1 interrupt whenever the QBHE flag in QSCI1SR is set. The interrupt is blocked by negating QBHEI. This bit refers to the queue locations SCTQ[8:15].<br>0 QBHE interrupt inhibited<br>1 Queue bottom-half empty (QBHE) interrupt enabled                                                                                                                                               |
| 8    | —     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 9    | QTE   | Queue transmit enable. When set, the transmit queue is enabled and the TDRE bit should be ignored by software. The TC bit is redefined to indicate when the entire queue is finished transmitting. When clear, the SCI1 functions as described in the previous sections and the bits related to the queue (Section 5.5 and its subsections) should be ignored by software with the exception of QTE.<br>0 Transmit queue is disabled<br>1 Transmit queue is enabled |

**Table 15-32. QSCI1CR Bit Descriptions (continued)**

| Bits  | Name | Description                                                                                                                                                                                                                                                                                                                                                                 |
|-------|------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 10    | QRE  | Queue receive enable. When set, the receive queue is enabled and the RDRF bit should be ignored by software. When clear, the SCI1 functions as described in the previous sections and the bits related to the queue (Section 5.5 and its subsections) should be ignored by software with the exception of QRE.<br>0 Receive queue is disabled<br>1 Receive queue is enabled |
| 11    | QTWE | Queue transmit wrap enable. When set, the transmit queue is allowed to restart transmitting from the top of the queue after reaching the bottom of the queue. After each wrap of the queue, QTWE is cleared by hardware.<br>0 Transmit queue wrap feature is disabled<br>1 Transmit queue wrap feature is enabled                                                           |
| 12:15 | QTSZ | Queue transfer size. The QTSZ bits allow programming the number of data frames to be transmitted. From 1 (QTSZ = 0b0000) to 16 (QTSZ = 0b1111) data frames can be specified. QTSZ is loaded into QPEND initially or when a wrap occurs.                                                                                                                                     |

### 15.8.2.2 QSCI1 Status Register (QSCI1SR)

**Figure 15-32. QSCI1 Status Register (QSCI1SR)**
**Table 15-33. QSCI1SR Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|------|------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:2  | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 3    | QOR  | Receiver queue overrun error. The QOR is set when a new data frame is ready to be transferred from the SC1DR to the queue and the queue is already full (QTHF or QBHF are still set). Data transfer is inhibited until QOR is cleared. Previous data transferred to the queue remains valid. Additional data received during a queue overrun condition is not lost provided the receive queue is re-enabled before OR (SC1SR) is set. The OR flag is set when a new data frame is received in the shifter but the data register (SC1DR) is still full. The data in the shifter that generated the OR assertion is overwritten by the next received data frame, but the data in the SC1DR is not lost.<br>0 The queue is empty before valid data is in the SC1DR<br>1 The queue is not empty when valid data is in the SC1DR |
| 4    | QTHF | Receiver queue top-half full. QTHF is set when the receive queue locations SCRQ[0:7] are completely filled with new data received via the serial shifter. QTHF is cleared when register QSCI1SR is read with QTHF set, followed by a write of QTHF to zero.<br>0 The queue locations SCRQ[0:7] are partially filled with newly received data or is empty<br>1 The queue locations SCRQ[0:7] are completely full of newly received data                                                                                                                                                                                                                                                                                                                                                                                      |

**Table 15-33. QSCI1SR Bit Descriptions (continued)**

| Bits  | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-------|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 5     | QBHF  | Receiver queue bottom-half full. QBHF is set when the receive queue locations SCRQ[8:15] are completely filled with new data received via the serial shifter. QBHF is cleared when register QSCI1SR is read with QBHF set, followed by a write of QBHF to zero.<br>0 The queue locations SCRQ[8:15] are partially filled with newly received data or is empty<br>1 The queue locations SCRQ[8:15] are completely full of newly received data    |
| 6     | QTHE  | Transmitter queue top-half empty. QTHE is set when all the data frames in the transmit queue locations SCTQ[0:7] have been transferred to the transmit serial shifter. QTHE is cleared when register QSCI1SR is read with QTHE set, followed by a write of QTHE to zero.<br>0 The queue locations SCTQ[0:7] still contain data to be sent to the transmit serial shifter<br>1 New data may now be written to the queue locations SCTQ[0:7]      |
| 7     | QBHE  | Transmitter queue bottom-half empty. QBHE is set when all the data frames in the transmit queue locations SCTQ[8:15] has been transferred to the transmit serial shifter. QBHE is cleared when register QSCI1SR is read with QBHE set, followed by a write of QBHE to zero.<br>0 The queue locations SCTQ[8:15] still contain data to be sent to the transmit serial shifter<br>1 New data may now be written to the queue locations SCTQ[8:15] |
| 8:11  | QRPNT | Queue receive pointer. QRPNT is a 4-bit counter used to indicate the position where the next valid data frame will be stored within the receive queue. This field is writable in test mode only; otherwise it is read-only.                                                                                                                                                                                                                     |
| 12:15 | QPEND | Queue pending. QPEND is a 4-bit decrementer used to indicate the number of data frames in the queue that are awaiting transfer to the SC1DR. This field is writable in test mode only; otherwise it is read-only. From 1 (QPEND = 0b0000) to 16 (or done, QPEND = 1111) data frames can be specified.                                                                                                                                           |

### 15.8.3 QSCI1 Transmitter Block Diagram

The block diagram of the enhancements to the SCI transmitter is shown in [Figure 15-33](#).

Figure 15-33. Queue Transmitter Block Enhancements

### 15.8.4 QSCI1 Additional Transmit Operation Features

- Available on a single SCI channel (SCI1) implemented by the queue transmit enable (QTE) bit set by software. When enabled, (QTE = 1) the TDRE bit should be ignored by software and the TC bit is redefined (as described later).
- When the queue is disabled (QTE = 0), the SCI functions in single buffer transfer mode where the queue size is set to one (QTSZ = 0000), and TDRE and TC function as previously defined. Locations SCTQ[0:15] can be used as general purpose 9-bit registers. All other bits pertaining to the queue should be ignored by software.
- Programmable queue up to 16 transmits (SCTQ[0:15]) which may allow for infinite and continuous transmits.
- Available transmit wrap function to prevent message breaks for transmits greater than 16. This is achieved by the transmit wrap enable (QTWE) bit. When QTWE is set, the hardware is allowed to

restart transmitting from the top of the queue (SCTQ0). After each wrap, QTWE is cleared by hardware.

- Transmissions of more than 16 data frames must be performed in multiples of 16 (QTSZ = 0b1111) except for the last set of transmissions. For any single non-continuous transmissions of 16 or less or the last transmit set composed of 16 or fewer data frames, programming of QTSZ to the corresponding value of 16 or less where QTWE = 0 is allowed.
- Interrupt generation when the top half (SCTQ[0:7]) of the queue has been emptied (QTHE) and the bottom half (SCTQ[8:15]) of the queue has been emptied (QBHE). This may allow for uninterrupted and continuous transmits by indicating to the CPU that it can begin refilling the queue portion that is now emptied.
  - The QTHE bit is set by hardware when the top half is empty or the transmission has completed. The QTHE bit is cleared when the QSCI1SR is read with QTHE set, followed by a write of QTHE to zero.
  - The QBHE bit is set by hardware when the bottom half is empty or the transmission has completed. The QBHE bit is cleared when the QSCI1SR is read with QBHE set, followed by a write of QBHE to zero.
  - In order to implement the transmit queue, QTE must be set (QSCI1CR), TE must be set (SCC1R1), QTHE must be cleared (QSCI1SR), and TDRE must be set (SC1SR).
- Enable and disable options for the interrupts QTHE and QBHE as controlled by QTHEI and QBHEI respectfully.
- Programmable 4-bit register queue transmit size (QTSZ) for configuring the queue to any size up to 16 transfers at a time. This value may be rewritten after transmission has started to allow for the wrap feature.
- 4-bit status register to indicate the number of data transfers pending (QPEND). This register counts down to all 0's where the next count rolls over to all 1's. This counter is writable in test mode; otherwise it is read-only.
- 4-bit counter (QTPNT) is used as a pointer to indicate the next data frame within the transmit queue to be loaded into the SC1DR. This counter is writable in test mode; otherwise it is read-only.
- A transmit complete (TC) bit re-defined when the queue is enabled (QTE = 1) to indicate when the entire queue (including when wrapped) is finished transmitting. This is indicated when QPEND = 1111 and the shifter has completed shifting data out. TC is cleared when the SCxSR is read with TC = 1 followed by a write to SCTQ[0:15]. If the queue is disabled (QTE = 0), the TC bit operates as originally designed.
- When the transmit queue is enabled (QTE = 1), writes to the transmit data register (SC1DR) have no effect.

## 15.8.5 QSCI1 Transmit Flow Chart Implementing the Queue

Figure 15-34. Queue Transmit Flow

Figure 15-35. Queue Transmit Software Flow

# 15.8.6 Example QSCI Transmit for 17 Data Bytes

Figure 15-36 below shows a transmission of 17 data frames. The bold type indicates the current value for QTPNT and QPEND. The italic type indicates the action just performed by hardware. Regular type indicates the actions that should be performed by software before the next event.

Figure 15-36. Queue Transmit Example for 17 Data Bytes

## 15.8.7 Example SCI Transmit for 25 Data Bytes

[Figure 15-37](#) below is an example of a transmission of 25 data frames.

① Transmit Queue Enabled  
QTSZ=1111 (16 Data Frames)

② QTHE Interrupt Received  
QTSZ=1111 (16 Data Frames)

Write QTSZ = 8 (16 + 9 = 25)  
Write SCTQ [0:7] for 8 More Data Frames  
Set QTWE  
Clear QTHE

 Data to be Transferred  
 Available Register Space

③ QBHE Interrupt Received  
(Wrap Occurred)  
QTSZ=1000 (9 Data Frames)

④ QTHE Interrupt Received  
QTSZ=1000 (9 Data Frames)

Load QPEND with QTSZ  
Clear QTWE  
Reset QTPNT  
Write SCTQ8  
Clear QBHE

Figure 15-37. Queue Transmit Example for 25 Data Frames

## 15.8.8 QSCI1 Receiver Block Diagram

The block diagram of the enhancements to the SCI receiver is shown below in [Figure 15-38](#).

Figure 15-38. Queue Receiver Block Enhancements

## 15.8.9 QSCI1 Additional Receive Operation Features

Additional QSCI1 features include:

- Available on a single SCI channel (SCI1) implemented by the queue receiver enable (QRE) bit set by software. When the queue is enabled, software should ignore the RDRF bit.
- When the queue is disabled (QRE = 0), the SCI functions in single buffer receive mode (as originally designed) and RDRF and OR function as previously defined. Locations SCRQ[0:15] can

be used as general purpose 9-bit registers. Software should ignore all other bits pertaining to the queue.

- Only data that has no errors (FE and PF both false) is allowed into the queue. The status flags FE and PF, if set, reflect the status of data not allowed into the queue. The receive queue is disabled until the error flags are cleared via the original SCI mechanism and the queue is re-initialized. The pointer QRPNT indicates the queue location where the data frame would have been stored.
- Queue size capable to receive up to 16 data frames (SCRQ[0:15]) which may allow for infinite and continuous receives.
- Interrupt generation can occur when the top half (SCRQ[0:7]) of the queue has been filled (QTHF) and the bottom half (SCRQ[8:15]) of the queue has been filled (QBHF). This may allow for uninterrupted and continuous receives by indicating to the CPU to start reading the queue portion that is now full.
  - The QTHF bit is set by hardware when the top half is full. The QTHF bit is cleared when the SCxSR is read with QTHF set, followed by a write of QTHF to zero.
  - The QBHF bit is set by hardware when the bottom half is full. The QBHF bit is cleared when the SCxSR is read with QBHF set, followed by a write of QBHF to zero.
- In order to implement the receive queue, the following conditions must be met: QRE must be set (QSCI1CR); RE must be set (SCC1R1); QOR and QTHF must be cleared (QSCI1SR); and OR, PF, and FE must be cleared (SC1SR).
- Enable and disable options for the interrupts QTHF and QBHF as controlled by the QTHFI and QBHFI, respectfully.
- 4-bit counter (QRPNT) is used as a pointer to indicate where the next valid data frame will be stored.
- A queue overrun error flag (QOR) to indicate when the queue is already full when another data frame is ready to be stored into the queue (similar to the OR bit in single buffer mode). The QOR bit can be set for QTHF = 1 or QBHF = 1, depending on where the store is being attempted.
- The queue can be exited when an idle line is used to indicate when a group of serial transmissions is finished. This can be achieved by using the ILIE bit to enable the interrupt when the IDLE flag is set. The CPU can then clear QRE and/or RE allowing the receiver queue to be exited.
- For receiver queue operation, IDLE is cleared when SC1SR is read with IDLE set, followed by a read of SCRQ[0:15].
- For receiver queue operation, NF is cleared when the SC1SR is read with NF set, followed by a read of SCRQ[0:15]. When noise occurs, the data is loaded into the receive queue, and operation continues unaffected. However, it may not be possible to determine which data frame in the receive queue caused the noise flag to be asserted.
- The queue is successfully filled (16 data frames) if error flags (FE and PF) are clear, QTHF and QBHF are set, and QRPNT is reset to all zeroes.
- QOR indicates that a new data frame has been received in the data register (SC1DR), but it cannot be placed into the receive queue due to either the QTHF or QBHF flag being set (QSCI1SR). Under this condition, the receive queue is disabled (QRE = 0). Software may service the receive queue and clear the appropriate flag (QTHF, QBHF). Data is not lost provided that the receive queue is re-enabled before OR (SC1SR) is set, which occurs when a new data frame is received in the shifter

but the data register (SC1DR) is still full. The data in the shifter that generated the OR assertion is overwritten by the next received data frame, but the data in the SC1DR is not lost.

## 15.8.10 QSCI1 Receive Flow Chart Implementing the Queue

### 15.8.12 Example QSCI1 Receive Operation of 17 Data Frames

Figure 15-41 shows an example receive operation of 17 data frames. The bold type indicates the current value for the QRPNT. Action of the queue may be followed by starting at the top of the figure and going left to right and then down the page.

Figure 15-41. Queue Receive Example for 17 Data Bytes

## Chapter 16

### CAN 2.0B Controller Module

The MPC561/MPC563 contains three CAN 2.0B controller modules (TouCAN). Each TouCAN is a communication controller that implements the Controller Area Network (CAN) protocol, an asynchronous communications protocol used in automotive and industrial control systems. It is a high speed (one Mbit/sec), short distance, priority based protocol that can run over a variety of mediums (for example, fiber optic cable or an unshielded twisted pair of wires). The TouCAN supports both the standard and extended identifier (ID) message formats specified in the CAN protocol specification, revision 2.0, part B. The third TouCAN has its signals muxed with MIO14 GPIO or QSMCM SCI2 signals. These signals are configured as GPIO inputs at reset and must be changed to TouCAN signals in the MIO before enabling the TouCAN.

Each TouCAN module contains 16 message buffers that are used for transmit and receive functions. It also contains message filters, which are used to qualify the received message IDs when comparing them to the receive buffer identifiers. [Figure 16-1](#) shows a block diagram of a TouCAN module.

**Figure 16-1. TouCAN Block Diagram**

### 16.1 Features

Each TouCAN module provides these features:

- Full implementation of CAN protocol specification, version 2.0 A/B
  - Standard data and remote frames (up to 109 bits long)
  - Extended data and remote frames (up to 127 bits long)

- Zero to eight bytes data length
- Programmable bit rate up to one Mbit/sec
- 16 Rx/Tx message buffers of 0-8 bytes data length
- Content-related addressing
- No read/write semaphores required
- Three programmable mask registers: global (for message buffers 0 through 13), special for message buffer 14, and special for message buffer 15
- Programmable transmit-first scheme: lowest ID or lowest buffer number
- “Time stamp”, based on 16-bit free-running timer
- Global network time, synchronized by a specific message
- Programmable I/O modes
- Maskable interrupts
- Independent of the transmission medium (external transceiver is assumed)
- Open network architecture
- Multimaster concept
- High immunity to EMI
- Short latency time for high-priority messages
- Low power sleep mode with programmable wakeup on bus activity
- Outputs have open drain drivers
- Support for SAE J1939 and SAE J2284
- Support for DeviceNet™ and Smart Distributed System

## 16.2 External Signals

Each TouCAN module interface to the external CAN bus consists of two signals: CNTX0 which transmits serial data, and CNRX0 which receives serial data.

**Figure 16-2. Typical CAN Network**

Each CAN station is connected physically to the CAN bus through an external transceiver. The transceiver provides the transmit drive, waveshaping, and receive/compare functions required for communicating on the CAN bus. It can also provide protection against damage to the TouCAN caused by a defective CAN bus or a defective CAN station.

### 16.2.1 TouCAN Signal Sharing

The CNTX0 and CNRX0 signals of TouCAN\_A and TouCAN\_B are available at all times. The CNTX0 and CNRX0 signals of TouCAN\_C are shared with MIO14 GPIO signals (MPIO32B11, MPIO32B12) or QSMCM SCI2 signals (TXD2/QGPO2, RXD2/QGPI2). The signal functions for these signals are controlled by the PDMCR2[TCNC] register.

#### NOTE

Only one function can be enabled on a signal at a time.

### 16.3 TouCAN Architecture

The TouCAN module uses a flexible design that allows each of its 16 message buffers to be designated either a transmit (Tx) buffer or a receive (Rx) buffer. In addition, to reduce the CPU overhead required for message handling, each message buffer is assigned an interrupt flag bit to indicate that the transmission or reception completed successfully.

### 16.3.1 Tx/Rx Message Buffer Structure

Figure 16-3 displays the extended (29-bit) ID message buffer structure.

Figure 16-3. Extended ID Message Buffer Structure

Figure 16-4 displays the standard (11-bit) ID message buffer structure.

Figure 16-4. Standard ID Message Buffer Structure

#### 16.3.1.1 Common Fields for Extended and Standard Format Frames

Table 16-1 describes the message buffer fields that are common to both extended and standard identifier format frames.

Table 16-1. Common Extended/Standard Format Frames

| Field      | Description                                                                                                                                         |
|------------|-----------------------------------------------------------------------------------------------------------------------------------------------------|
| Time Stamp | Contains a copy of the high byte of the free running timer, which is captured at the beginning of the identifier field of the frame on the CAN bus. |
| Code       | Refer to <a href="#">Table 16-2</a> and <a href="#">Table 16-3</a> .                                                                                |

**Table 16-1. Common Extended/Standard Format Frames (continued)**

| Field       | Description                                                                                                                                                                                                                                                                                                                    |
|-------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Length (Rx) | Length (in bytes) of the Rx data stored in offset 0x6 through 0xD of the buffer. This field is written by the TouCAN module, copied from the DLC (data length code) field of the received frame.                                                                                                                               |
| Length (Tx) | Length (in bytes) of the data to be transmitted, located in offset 0x6 through 0xD of the buffer. This field is written by the CPU and is used as the DLC field value. If RTR (remote transmission request) = 1, the frame is a remote frame and will be transmitted without data field, regardless of the value in Tx length. |
| Data        | This field can store up to eight data bytes for a frame. For Rx frames, the data is stored as it is received from the bus. For Tx frames, the CPU provides the data to be transmitted within the frame.                                                                                                                        |
| Reserved    | The CPU controls access to this word entry field (16 bits).                                                                                                                                                                                                                                                                    |

**Table 16-2. Message Buffer Codes for Receive Buffers**

| Rx Code Before Rx New Frame | Description                                                                                                          | Rx Code After Rx New Frame | Comment                                                              |
|-----------------------------|----------------------------------------------------------------------------------------------------------------------|----------------------------|----------------------------------------------------------------------|
| 0b0000                      | NOT ACTIVE — message buffer is not active.                                                                           | —                          | —                                                                    |
| 0b0100                      | EMPTY — message buffer is active and empty.                                                                          | 0b0010                     | —                                                                    |
| 0b0010                      | FULL — message buffer is full.                                                                                       | 0b0110                     | If a CPU read occurs before the new frame, new receive code is 0010. |
| 0b0110                      | OVERRUN — additional frame was received into a full buffer before the CPU read the first one.                        |                            |                                                                      |
| 0b0XY1 <sup>1</sup>         | BUSY — message buffer is now being filled with a new receive frame. This condition will be cleared within 20 cycles. | 0b0010                     | An empty buffer was filled (XY was 10).                              |
|                             |                                                                                                                      | 0b0110                     | A full/overflow buffer was filled (Y was 1).                         |

<sup>1</sup> For Tx message buffers, upon read, the BUSY bit should be ignored.

**Table 16-3. Message Buffer Codes for Transmit Buffers**

| RTR | Initial Tx Code     | Description                                                                                                   | Code After Successful Transmission |
|-----|---------------------|---------------------------------------------------------------------------------------------------------------|------------------------------------|
| x   | 0b1000              | Message buffer not ready for transmit.                                                                        | —                                  |
| 0   | 0b1100              | Data frame to be transmitted once, unconditionally.                                                           | 0b1000                             |
| 1   | 0b1100              | Remote frame to be transmitted once, and message buffer becomes an Rx message buffer for data frames.         | 0b0100                             |
| 0   | 0b1010 <sup>1</sup> | Data frame to be transmitted only as a response to a remote frame, always.                                    | 0b1010                             |
| 0   | 0b1110              | Data frame to be transmitted only once, unconditionally, and then only as a response to remote frame, always. | 0b1010                             |

<sup>1</sup> When a matching remote request frame is detected, the code for such a message buffer is changed to be 0b1110.

### 16.3.1.2 Fields for Extended Format Frames

Table 16-4 describes the message buffer fields used only for extended identifier format frames.

**Table 16-4. Extended Format Frames**

| Field                             | Description                                                                                                                                                     |
|-----------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ID[28:18]/[17:15]                 | Contains the 14 most significant bits of the extended identifier, located in the ID_HIGH word of the message buffer.                                            |
| Substitute Remote Request (SRR)   | Contains a fixed recessive bit, used only in extended format. Should be set to one for Tx buffers. It will be stored as received on the CAN bus for Rx buffers. |
| ID Extended (IDE)                 | If extended format frame is used, this field should be set to one. If zero, standard format frame should be used.                                               |
| ID[14:0]                          | Bits [14:0] of the extended identifier, located in the ID_LOW word of the message buffer.                                                                       |
| Remote Transmission Request (RTR) | This bit is located in the least significant bit of the ID_LOW word of the message buffer<br>0 Data Frame<br>1 Remote Frame                                     |

### 16.3.1.3 Fields for Standard Format Frames

Table 16-5 describes the message buffer fields used only for standard identifier format frames.

**Table 16-5. Standard Format Frames**

| Field                 | Description                                                                                                                                                                                                                                                                                                           |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 16-bit Time Stamp     | The ID_LOW word, which is not needed for standard format, is used in a standard format buffer to store the 16-bit value of the free-running timer which is captured at the beginning of the identifier field of the frame on the CAN bus.                                                                             |
| ID[28:18]             | Contains bits [28:18] of the identifier, located in the ID_HIGH word of the message buffer. The four least significant bits in this register (corresponding to the IDE bit and ID[17:15] for an extended identifier message) must all be written as logic zeros to ensure proper operation of the TouCAN.             |
| RTR                   | This bit is located in the ID_HIGH word of the message buffer;<br>0 Data Frame<br>1 Remote Frame                                                                                                                                                                                                                      |
| RTR/SRR Bit Treatment | If the TouCAN transmits this bit as a one and receives it as a zero, an “arbitration loss” is indicated. If the TouCAN transmits this bit as a zero and receives it as a one, a bit error is indicated. If the TouCAN transmits a value and receives a matching response, a successful bit transmission is indicated. |

### 16.3.1.4 Serial Message Buffers

To allow double buffering of messages, the TouCAN has two shadow buffers called serial message buffers. The TouCAN uses these two buffers for buffering both received messages and messages to be transmitted. Only one serial message buffer is active at a time, and its function depends upon the operation of the TouCAN at that time. These buffers are not accessible or visible to the user.

### 16.3.1.5 Message Buffer Activation/Deactivation Mechanism

Each message buffer must be activated once it is configured for the desired operation. A buffer is activated by writing the appropriate code to the control/status word for that buffer. Once the buffer is activated, it will start the normal transmit and receive processes.

A buffer is deactivated by writing the appropriate deactivation code to the control/status word for that buffer. A buffer is typically deactivated to reconfigure the buffer (for example to change the buffer's function from Rx to Tx or Tx to Rx). The buffer should also be deactivated before changing a receive buffer's message identifier or before loading a new message to be transmitted into a transmit buffer.

For more details on activation and deactivation of message buffers and the effects on message buffer operation, refer to [Section 16.4, "TouCAN Operation."](#)

### 16.3.1.6 Message Buffer Lock/Release/Busy Mechanism

In addition to the activation/deactivation mechanism, the TouCAN also uses a lock/release/busy mechanism to ensure data coherency during the receive process. The mechanism includes a lock status for each message buffer and uses the two serial message buffers to facilitate frame transfers within the TouCAN.

Reading the control/status word of a receive message buffer triggers the lock for that buffer. While locked, a received message cannot be transferred into that buffer from one of the serial message buffers.

If a message transfer between the message buffer and a serial message buffer is in progress when the control/status word is read, the BUSY status is indicated in the code field, and the lock is not activated.

The user can release the lock on a message buffer in one of two ways. Reading the control/status word of another message buffer locks that buffer, releasing the previously locked buffer. A global release can also be performed on any locked message buffer by reading the free-running timer.

Once a lock is released, any message transfers between a serial message buffer and a message buffer that were delayed due to that buffer being locked will take place. For more details on the message buffer locking mechanism, and the effects on message buffer operation, refer to [Section 16.4, "TouCAN Operation."](#)

## 16.3.2 Receive Mask Registers

The receive mask registers are used as acceptance masks for received frame IDs. The following masks are defined:

- A global mask, used for receive buffers 0-13
- Two separate masks for buffers 14 and 15

The value of the mask registers should not be changed during normal operation. If the mask register data is changed after the masked identifier of a received message is matched to a locked message buffer, that message will be transferred into that message buffer once it is unlocked, regardless of whether that message's masked identifier still matches the receive buffer identifier. [Table 16-6](#) shows mask bit values.

**Table 16-6. Receive Mask Register Bit Values**

| Mask Bit | Values                                                                                   |
|----------|------------------------------------------------------------------------------------------|
| 0        | The corresponding incoming ID bit is “don’t care”                                        |
| 1        | The corresponding ID bit is checked against the incoming ID bit to see if a match exists |

Table 16-7 shows mask examples for normal and extended messages. Refer to [Section 16.7, “Programming Model”](#) for more information on Rx mask registers.

**Table 16-7. Mask Examples for Normal/Extended Messages**

| Message Buffer (MB)/Mask | Base ID ID[28:18]     | IDE | Extended ID ID[17:0]              | Match           |
|--------------------------|-----------------------|-----|-----------------------------------|-----------------|
| MB2                      | 1 1 1 1 1 1 1 1 0 0 0 | 0   | —                                 | —               |
| MB3                      | 1 1 1 1 1 1 1 1 0 0 0 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | —               |
| MB4                      | 0 0 0 0 0 0 1 1 1 1 1 | 0   | —                                 | —               |
| MB5                      | 0 0 0 0 0 0 1 1 1 0 1 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | —               |
| MB14                     | 1 1 1 1 1 1 1 1 0 0 0 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | —               |
| Rx Global Mask           | 1 1 1 1 1 1 1 1 1 1 0 |     | 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0 0 1 | —               |
| Rx Message In            | 1 1 1 1 1 1 1 1 0 0 1 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | 3 <sup>1</sup>  |
|                          | 1 1 1 1 1 1 1 1 0 0 1 | 0   | —                                 | 2 <sup>2</sup>  |
|                          | 1 1 1 1 1 1 1 1 0 0 1 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 0   | — <sup>3</sup>  |
|                          | 0 1 1 1 1 1 1 1 0 0 0 | 0   | —                                 | — <sup>4</sup>  |
|                          | 0 1 1 1 1 1 1 1 0 0 0 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | — <sup>5</sup>  |
| Rx 14 Mask               | 0 1 1 1 1 1 1 1 1 1 1 |     | 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0 0 0 | —               |

|                          | 0 1 1 1 1 1 1 1 0 0 0 | 1   | 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1   | 14 <sup>7</sup> |

<sup>1</sup> Match for extended format (MB3).

<sup>2</sup> Match for standard format (MB2).

<sup>3</sup> No match for MB3 because of ID0.

<sup>4</sup> No match for MB2 because of ID28.

<sup>5</sup> No match for MB3 because of ID28, match for MB14.

<sup>6</sup> No match for MB14 because of ID27.

<sup>7</sup> Match for MB14.

### 16.3.3 Bit Timing

The TouCAN module uses three 8-bit registers to set up the bit timing parameters required by the CAN protocol. Control registers one and two (CANCTRL1, CANCTRL2) contain the PROPSEG, PSEG1, PSEG2, and the RJW fields that allow configuration of the bit timing parameters. The prescaler divide register (PRES DIV) allows selection of the ratio used to derive the serial clock (S-clock) from the system clock. The time quanta clock operates at the S-clock frequency. [Table 16-8](#) provides examples of system clock, CAN bit rate, and S-clock bit timing parameters, and [Figure 16-5](#) shows the relationship between

the system clock and the CAN bit segments. Refer to [Section 16.7, “Programming Model,”](#) for more information on the bit timing registers.

**Figure 16-5. Relationship between System Clock and CAN Bit Segments**

A bit is divided into four separate non-overlapping time segments called SYNC\_SEG, PROPSEG, PSEG1, and PSEG2. These are illustrated in [Figure 16-5](#). The period of the nominal bit time (NBT) is the sum of the segment durations:

$$t_{NBT} = t_{SYNC\_SEG} + t_{PROPSEG} + t_{PSEG1} + t_{PSEG2}$$

The sample point indicated in [Figure 16-5](#) is the position of the actual sample point if a single sample per bit is selected (CANCTRL1[SAMP] bit = 0). If three samples per bit are selected, the sample point indicated in [Figure 16-5](#) marks the position of the final sample.

**Table 16-8. Example System Clock, CAN Bit Rate, and S-Clock Frequencies**

| System Clock Frequency (MHz) | CAN Bit Rate (MHz) | Possible S-Clock Frequency (MHz) | Possible Number of Time Quanta/Bit | PRES DIV Value + 1 |
|------------------------------|--------------------|----------------------------------|------------------------------------|--------------------|
| 56                           | 1                  | 56                               | 56                                 | 1                  |
| 40                           | 1                  | 40                               | 40                                 | 1                  |
| 25                           | 1                  | 25                               | 25                                 | 1                  |
| 20                           | 1                  | 10, 20                           | 10, 20                             | 2, 1               |
| 16                           | 1                  | 8, 16                            | 8, 16                              | 2, 1               |
| 56                           | 0.500              | 56                               | 118                                | 1                  |
| 40                           | 0.500              | 40                               | 80                                 | 1                  |
| 25                           | 0.500              | 25                               | 50                                 | 1                  |
| 20                           | 0.500              | 1, 2, 2.5                        | 2, 4, 5                            | 20, 10, 8          |

**Table 16-8. Example System Clock, CAN Bit Rate, and S-Clock Frequencies (continued)**

| System Clock Frequency (MHz) | CAN Bit Rate (MHz) | Possible S-Clock Frequency (MHz) | Possible Number of Time Quanta/Bit | PRES DIV Value + 1 |
|------------------------------|--------------------|----------------------------------|------------------------------------|--------------------|
| 16                           | 0.500              | 1, 2                             | 2, 4                               | 16, 8              |
| 56                           | 0.125              | 1, 2                             | 8, 16                              | 56, 28             |
| 40                           | 0.125              | 1, 2                             | 8, 16                              | 40, 20             |
| 25                           | 0.125              | 1, 1.25, 2.5                     | 8, 10, 20                          | 25, 20, 10         |
| 20                           | 0.125              | 1, 2, 2.5                        | 8, 16, 20                          | 20, 10, 8          |
| 16                           | 0.125              | 1, 2                             | 8, 16                              | 16, 8              |

### 16.3.3.1 Configuring the TouCAN Bit Timing

The following considerations must be observed when programming bit timing functions.

- If the programmed PRES DIV value results in a single system clock per one time quantum, then the PSEG2 field in CANCTRL2 register must not be programmed to zero.
- If the programmed PRES DIV value results in a single system clock per one time quantum, then the information processing time (IPT) equals three time quanta; otherwise it equals two time quanta. If PSEG2 equals two, then the TouCAN transmits one time quantum late relative to the scheduled sync segment.
- If the prescaler and bit timing control fields are programmed to values that result in fewer than 10 system clock periods per CAN bit time and the CAN bus loading is 100%, then any time the rising edge of a start-of-frame (SOF) symbol transmitted by another node occurs during the third bit of the intermission between messages, the TouCAN may not be able to prepare a message buffer for transmission in time to begin its own transmission and arbitrate against the message which transmitted the early SOF.
- The TouCAN bit time must be programmed to be greater than or equal to nine system clocks, or correct operation is not guaranteed. The duration of the synchronization segment, SYNC\_SEG, is not programmable and is fixed at one time quantum.

### 16.3.4 Error Counters

The TouCAN has two error counters, the transmit (Tx) error counter and the receive (Rx) error counter. Refer to [Section 16.7, “Programming Model,”](#) for more information on error counters. The rules for increasing and decreasing these counters are described in the CAN protocol, and are fully implemented in the TouCAN. Each counter has the following features:

- Eight-bit up/down-counter
- Increment by eight (Rx error counter also increments by one)
- Decrement by one
- Avoid decrement when equal to zero
- Rx error counter reset to a value between 119 and 127 inclusive, when the TouCAN transitions from error passive to error active

- Following reset, both counters reset to zero
- Detect values for error passive, bus off and error active transitions
- Cascade usage of Tx error counter with an additional internal counter to detect the 128 occurrences of 11 consecutive recessive bits necessary to transition from bus off into error active.

Both counters are read-only (except in test/freeze/halt modes).

The TouCAN responds to any bus state as described in the CAN protocol, transmitting an error active or error passive flag, delaying its transmission start time (error passive) and avoiding any influence on the bus when in the bus off state. The following are the basic rules for TouCAN bus state transitions:

- If the value of the Tx error counter or Rx error counter increments to a value greater than or equal to 128, the fault confinement state (FCS[1:0]) field in the error status register is updated to reflect an error passive state.
- If the TouCAN is in an error passive state, and either the Tx error counter or Rx error counter decrements to a value less than or equal to 127 while the other error counter already satisfies this condition, the FCS[1:0] field in the error status register is updated to reflect an error active state.
- If the value of the Tx error counter increases to a value greater than 255, the FCS[1:0] field in the error status register is updated to reflect a bus off state, and an interrupt may be issued. The value of the Tx error counter is reset to zero.
- If the TouCAN is in the bus off state, the Tx error counter and an additional internal counter are cascaded to count 128 occurrences of 11 consecutive recessive bits on the bus. To do this, the Tx error counter is first reset to zero, and then the internal counter begins counting consecutive recessive bits. Each time the internal counter counts 11 consecutive recessive bits, the Tx error counter is incremented by one and the internal counter is reset to zero. When the Tx error counter reaches the value of 128, the FCS[1:0] field in the error status register is updated to be error active, and both error counters are reset to zero. Any time a dominant bit is detected following a stream of less than 11 consecutive recessive bits, the internal counter resets itself to zero but does not affect the Tx error counter value.
- If only one node is operating in a system, the Tx error counter is incremented with each message it attempts to transmit, due to the resulting acknowledgment errors. However, acknowledgment errors never cause the TouCAN to change from the error passive state to the bus off state.
- If the Rx error counter increments to a value greater than 127, it stops incrementing, even if more errors are detected while being a receiver. After the next successful message reception, the counter is reset to a value between 119 and 127, to enable a return to the error active state.

The three basic states and the transition behavior of the CAN controller are shown in [Figure 16-6](#).

Figure 16-6. CAN Controller State Diagram

### 16.3.5 Time Stamp

The value of the free-running 16-bit timer is sampled at the beginning of the identifier field on the CAN bus. For a message being received, the time stamp is stored in the time stamp entry of the receive message buffer at the time the message is written into that buffer. For a message being transmitted, the time stamp entry is written into the transmit message buffer once the transmission has completed successfully.

The free-running timer can optionally be reset upon the reception of a frame into message buffer 0. This feature allows network time synchronization to be performed.

## 16.4 TouCAN Operation

The basic operation of the TouCAN can be divided into four areas:

- Reset
- Initialization of the module
- Transmit message handling
- Receive message handling

Example sequences for performing each of these processes is given in the following paragraphs.

### 16.4.1 TouCAN Reset

The TouCAN can be reset in two ways:

- Hard reset of the module via  $\overline{\text{SRESET}}$ .
- Soft reset of the module, using the SOFTRST bit in the module configuration register

Following the negation of reset, the TouCAN is not synchronized with the CAN bus, and the HALT, FRZ, and FRZACK bits in the module configuration register are set. In this state, the TouCAN does not initiate frame transmissions or receive any frames from the CAN bus. The contents of the message buffers are not changed following reset.

Any configuration change or initialization requires that the TouCAN be frozen by either the assertion of the HALT bit in the module configuration register or by reset.

## 16.4.2 TouCAN Initialization

Initialization of the TouCAN includes the initial configuration of the message buffers and configuration of the CAN communication parameters following a reset, as well as any reconfiguration which may be required during operation. The following is a general initialization sequence for the TouCAN:

1. Initialize all operation modes
  - a) Initialize the transmit and receive pin modes in CANCTRL0
  - b) Initialize the bit timing parameters PROPSEG, PSEG1, PSEG2, and RJW in CANCTRL1 and CANCTRL2
  - c) Select the S-clock rate by programming the PRES DIV register
  - d) Select the internal arbitration mode (LBUF bit in CANCTRL1)
2. Initialize message buffers
  - a) The control/status word of all message buffers must be written either as an active or inactive message buffer.
  - b) All other entries in each message buffer should be initialized as required
3. Initialize mask registers for acceptance mask as required
4. Initialize TouCAN interrupt handler
  - a) Initialize the interrupt configuration register (CANICR) with a specific request level
  - b) Set the required mask bits in the IMASK register (for all message buffer interrupts), in CANCTRL0 (for bus off and error interrupts), and in CANMCR for the WAKE interrupt
5. Negate the HALT bit in the module configuration register. At this point, the TouCAN attempts to synchronize with the CAN bus

### NOTE

In both the transmit and receive processes, the first action in preparing a message buffer must be to deactivate the buffer by setting its code field to the proper value. This step is mandatory to ensure data coherency.

## 16.4.3 Transmit Process

The transmit process includes preparation of a message buffer for transmission, as well as the internal steps performed by the TouCAN to decide which message to transmit. This involves loading the message and ID to be transmitted into a message buffer and then activating that buffer as an active transmit buffer. Once this is done, the TouCAN performs all additional steps necessary to transmit the message onto the CAN bus.

The user should prepare or change a message buffer for transmission by executing the following steps.

1. Write the control/status word to hold the transmit buffer inactive (code = 0b1000)
2. Write the ID\_HIGH and ID\_LOW words
3. Write the data bytes
4. Write the control/status word (active Tx code, Tx length)

### NOTE

Steps 1 and 4 are mandatory to ensure data coherency.

Once an active transmit code is written to a transmit message buffer, that buffer begins participating in an internal arbitration process as soon as the receiver senses that the CAN bus is free, or at the inter-frame space. If there are multiple messages awaiting transmission, this internal arbitration process selects the message buffer from which the next frame is transmitted.

When this process is over and a message buffer is selected for transmission, the frame from that message buffer is transferred to the serial message buffer for transmission.

The TouCAN transmits no more than eight data bytes, even if the transmit length contains a value greater than eight.

At the end of a successful transmission, the value of the free-running timer (which was captured at the beginning of the identifier field on the CAN bus), is written into the time stamp field in the message buffer. The code field in the control/status word of the message buffer is updated and a status flag is set in the IFLAG register.

#### 16.4.3.1 Transmit Message Buffer Deactivation

Any write access to the control/status word of a transmit message buffer during the process of selecting a message buffer for transmission immediately deactivates that message buffer, removing it from the transmission process.

If the transmit message buffer is deactivated while a message is being transferred from it to a serial message buffer, the message is not transmitted.

If the transmit message buffer is deactivated after the message is transferred to the serial message buffer, the message is transmitted, but no interrupt is requested, and the transmit code is not updated.

If a message buffer containing the lowest ID is deactivated while that message is undergoing the internal arbitration process to determine which message should be sent, then that message may not be transmitted.

#### 16.4.3.2 Reception of Transmitted Frames

The TouCAN receives a frame it has transmitted if an empty message buffer with a matching identifier exists.

#### 16.4.4 Receive Process

During the receive process, the following events occur:

- The user configures the message buffers for reception
- The TouCAN transfers received messages from the serial message buffers to the receive message buffers with matching IDs
- The user retrieves these messages

The user should prepare or change a message buffer for frame reception by executing the following steps.

1. Write the control/status word to hold the receive buffer inactive (code = 0b0000)
2. Write the ID\_HIGH and ID\_LOW words
3. Write the control/status word to mark the receive message buffer as active and empty

#### NOTE

Steps 1 and 3 are mandatory for data coherency.

Once these steps are performed, the message buffer functions as an active receive buffer and participates in the internal matching process, which takes place every time the TouCAN receives an error-free frame. In this process, all active receive buffers compare their ID value to the newly received one. If a match is detected, the following actions occur:

1. The frame is transferred to the first (lowest entry) matching receive message buffer
2. The value of the free-running timer (captured at the beginning of the identifier field on the CAN bus) is written into the time stamp field in the message buffer
3. The ID field, data field, and Rx length field are stored
4. The code field is updated
5. The status flag is set in the IFLAG register

The user should read a received frame from its message buffer in the following order:

1. Control/status word (mandatory, as it activates the internal lock for this buffer)
2. ID (optional, since it is needed only if a mask was used)
3. Data field word(s)
4. Free-running timer (optional, as it releases the internal lock)

If the free running timer is not read, that message buffer remains locked until the read process starts for another message buffer. Only a single message buffer is locked at a time. When a received message is read, the only mandatory read operation is that of the control/status word. This ensures data coherency.

If the BUSY bit is set in the message buffer code, the CPU should defer accessing that buffer until this bit is negated. Refer to [Table 16-2](#).

#### NOTE

The user should check the status of a message buffer by reading the status flag in the IFLAG register and not by reading the control/status word code field for that message buffer. This prevents the buffer from being locked inadvertently.

Because the received identifier field is always stored in the matching receive message buffer, the contents of the identifier field in a receive message buffer may change if one or more of the ID bits are masked.

### 16.4.4.1 Receive Message Buffer Deactivation

Any write access to the control/status word of a receive message buffer during the process of selecting a message buffer for reception immediately deactivates that message buffer, removing it from the reception process.

If a receive message buffer is deactivated while a message is being transferred into it, the transfer is halted and no interrupt is requested. If this occurs, that receive message buffer may contain mixed data from two different frames.

The CPU should not write data into a receive message buffer. If this occurs while a message is being transferred from a serial message buffer, the control/status word will reflect a full or overrun condition, but no interrupt is requested.

### 16.4.4.2 Locking and Releasing Message Buffers

The lock/release/busy mechanism is designed to guarantee data coherency during the receive process. The following examples demonstrate how the lock/release/busy mechanism affects TouCAN operation:

1. Reading a control/status word of a message buffer triggers a lock for that message buffer. A new received message frame which matches the message buffer cannot be written into this message buffer while it is locked.
2. To release a locked message buffer, the CPU either locks another message buffer by reading its control/status word or globally releases any locked message buffer by reading the free-running timer.
3. If a receive frame with a matching ID is received during the time the message buffer is locked, the receive frame is not immediately transferred into that message buffer, but remains in the serial message buffer. There is no indication when this occurs.
4. When a locked message buffer is released, if a frame with a matching identifier exists within the serial message buffer, then this frame is transferred to the matching message buffer.
5. If two or more receive frames with matching IDs are received while a message buffer with a matching ID is locked, the last received frame with that ID is kept within the serial message buffer, while all preceding ones are lost. There is no indication when this occurs.
6. If the control/status word of a receive message buffer is read while a frame is being transferred from a serial message buffer, the BUSY code is indicated. The user should wait until this code is cleared before continuing to read from the message buffer to ensure data coherency. In this situation, the read of the control/status word does not lock the message buffer.

Polling the control/status word of a receive message buffer can lock it, preventing a message from being transferred into that buffer. If the control/status word of a receive message buffer is read, it should be followed by a read of the control/status word of another buffer, or by a read of the free-running timer, to ensure that the locked buffer is unlocked.

### 16.4.5 Remote Frames

The remote frame is a message frame that is transmitted to request a data frame. The TouCAN can be configured to transmit a data frame automatically in response to a remote frame, or to transmit a remote frame and then wait for the responding data frame to be received.

To transmit a remote frame, a message buffer is initialized as a transmit message buffer with the RTR bit set to one. Once this remote frame is transmitted successfully, the transmit message buffer automatically becomes a receive message buffer, with the same ID as the remote frame that was transmitted.

When the TouCAN receives a remote frame, it compares the remote frame ID to the IDs of all transmit message buffers programmed with a code of 1010. If there is an exact matching ID, the data frame in that message buffer is transmitted. If the RTR bit in the matching transmit message buffer is set, the TouCAN transmits a remote frame as a response.

A received remote frame is not stored in a receive message buffer. It is only used to trigger the automatic transmission of a frame in response. The mask registers are not used in remote frame ID matching. All ID bits (except RTR) of the incoming received frame must match for the remote frame to trigger a response transmission.

### 16.4.6 Overload Frames

The TouCAN does not initiate overload frame transmissions unless it detects the following conditions on the CAN bus:

- A dominant bit is the first or second bit of intermission
- A dominant bit is the seventh (last) bit of the end-of-frame (EOF) field in receive frames
- A dominant bit is the eighth (last) bit of the error frame delimiter or overload frame delimiter

## 16.5 Special Operating Modes

The TouCAN module has three special operating modes:

- Debug mode
- Low-power stop mode
- Auto power save mode

### 16.5.1 Debug Mode

Debug mode is entered when the FRZ1 bit in CANMCR is set and one of the following events occurs:

- The HALT bit in the CANMCR is set; or
- The IMB3 FREEZE line is asserted

Once entry into debug mode is requested, the TouCAN waits until an intermission or idle condition exists on the CAN bus, or until the TouCAN enters the error passive or bus off state. Once one of these conditions exists, the TouCAN waits for the completion of all internal activity. Once this happens, the following events occur:

- The TouCAN stops transmitting or receiving frames
- The prescaler is disabled, thus halting all CAN bus communication
- The TouCAN ignores its Rx signals and drives its Tx signals as recessive
- The TouCAN loses synchronization with the CAN bus and the NOTRDY and FRZACK bits in CANMCR are set
- The CPU is allowed to read and write the error counter registers

After engaging one of the mechanisms to place the TouCAN in debug mode, the FRZACK bit must be set before accessing any other registers in the TouCAN; otherwise unpredictable operation may occur.

To exit debug mode, the IMB3 FREEZE line must be negated or the HALT bit in CANMCR must be cleared.

Once debug mode is exited, the TouCAN resynchronizes with the CAN bus by waiting for 11 consecutive recessive bits before beginning to participate in CAN bus communication.

## 16.5.2 Low-Power Stop Mode

Before entering low-power stop mode, the TouCAN waits for the CAN bus to be in an idle state, or for the third bit of intermission to be recessive. The TouCAN then waits for the completion of all internal activity (except in the CAN bus interface) to be complete. Then the following events occur:

- The TouCAN shuts down its clocks, stopping most internal circuits, thus achieving maximum power savings
- The bus interface unit continues to operate, allowing the CPU to access the module configuration register
- The TouCAN ignores its Rx signals and drives its Tx signals as recessive
- The TouCAN loses synchronization with the CAN bus, and the STOPACK and NOTRDY bits in the module configuration register are set

To exit low-power stop mode:

- Reset the TouCAN either by asserting one of the IMB3 reset lines or by asserting the SOFTRST bit CANMCR
- Clear the STOP bit in CANMCR
- The TouCAN module can optionally exit low-power stop mode via the self wake mechanism. If the SELFWAKE bit in CANMCR was set at the time the TouCAN entered stop mode, then upon detection of a recessive to dominant transition on the CAN bus, the TouCAN clears the STOP bit in CANMCR and its clocks begin running.

When the TouCAN is in low-power stop mode, a recessive to dominant transition on the CAN bus causes the WAKEINT bit in the error and status register (ESTAT) to be set. This event generates an interrupt if the WAKEMSK bit in CANMCR is set.

Consider the following notes regarding low-power stop mode:

- When the self wake mechanism is activated, the TouCAN tries to receive the frame that woke it up. (It assumes that the dominant bit detected is a start-of-frame bit.) It will not arbitrate for the CAN bus at this time.
- If the STOP bit is set while the TouCAN is in the bus off state, then the TouCAN enters low-power stop mode and stops counting recessive bit times. The count continues when STOP is cleared.
- To place the TouCAN in low-power stop mode with the self wake mechanism engaged, write to CANMCR with both STOP and SELFWAKE set, and then wait for the TouCAN to set the STOPACK bit.
- To take the TouCAN out of low-power stop mode when the self wake mechanism is enabled, write to CANMCR with both STOP and SELFWAKE clear, and then wait for the TouCAN to clear the STOPACK bit.
- The SELFWAKE bit should not be set after the TouCAN has already entered low-power stop mode.
- If both STOP and SELFWAKE are set and a recessive to dominant edge immediately occurs on the CAN bus, the TouCAN may never set the STOPACK bit, and the STOP bit will be cleared.
- To prevent old frames from being sent when the TouCAN awakes from low-power stop mode via the self wake mechanism, disable all transmit sources, including transmit buffers configured for remote request responses, before placing the TouCAN in low-power stop mode.
- If the TouCAN is in debug mode when the STOP bit is set, the TouCAN assumes that debug mode should be exited. As a result, it tries to synchronize with the CAN bus, and only then does it await the conditions required for entry into low-power stop mode.
- Unlike other modules, the TouCAN does not come out of reset in low-power stop mode. The basic TouCAN initialization procedure should be executed before placing the module in low-power stop mode. (Refer to [Section 16.4.2, “TouCAN Initialization.”](#))
- If the TouCAN is in low-power stop mode with the self wake mechanism engaged and is operating with a single system clock per time quantum, there can be extreme cases in which the TouCAN would wake-up on a recessive to dominant edge which may not conform to the CAN protocol. TouCAN synchronization is shifted one time quantum from the wake-up event. This shift lasts until the next recessive-to-dominant edge, which resynchronizes the TouCAN to be in conformance with the CAN protocol. The same holds true when the TouCAN is in auto power save mode and awakens on a recessive to dominant edge.

### 16.5.3 Auto Power Save Mode

Auto power save mode enables normal operation with optimized power savings. Once the auto power save (APS) bit in CANMCR is set, the TouCAN looks for a set of conditions in which there is no need for the clocks to be running. If these conditions are met, the TouCAN stops its clocks, thus saving power. The following conditions activate auto power save mode:

- No Rx/Tx frame in progress
- No transfer of Rx/Tx frames to and from a serial message buffer, and no Tx frame awaiting transmission in any message buffer
- No CPU access to the TouCAN module

- The TouCAN is not in debug mode, low-power stop mode, or the bus off state

While its clocks are stopped, if the TouCAN senses that any one of the aforementioned conditions is no longer true, it restarts its clocks. The TouCAN then continues to monitor these conditions and stops or restarts its clocks accordingly.

## 16.6 Interrupts

The TouCAN can generate one interrupt level to be passed to the CPU. This level is programmed into the priority level bits in the interrupt configuration register (CANICR). This value determines which interrupt signal is driven onto the bus when an interrupt is requested.

Each one of the 16 message buffers can be an interrupt source, if its corresponding IMASK bit is set. There is no distinction between transmit and receive interrupts for a particular buffer. Each of the buffers is assigned a bit in the IFLAG register. An IFLAG bit is set when the corresponding buffer completes a successful transmission/reception. An IFLAG bit is cleared when the CPU reads IFLAG while the associated bit is set, and then writes it back as zero (and no new event of the same type occurs between the read and the write actions).

The other three interrupt sources (bus off, error and wake up) act in the same way, and have flag bits located in the error and status register (ESTAT). The bus off and error interrupt mask bits (BOFFMSK and ERRMSK) are located in CANCTRL0, and the wake up interrupt mask bit (WAKEMSK) is located in the module configuration register. Refer to [Section 16.7, “Programming Model,”](#) for more information on these registers.

The TouCAN module is capable of generating one of the 32 possible interrupt levels on the IMB3. The 32 interrupt levels are time multiplexed on the IMB3 IRQ[0:7] lines. All interrupt sources place their asserted level on a time multiplexed bus during four different time slots, with eight levels communicated per slot. The ILBS[0:1] signals indicate which group of eight are being driven on the interrupt request lines.

**Table 16-9. Interrupt Levels**

| ILBS[0:1] | Levels |
|-----------|--------|
| 00        | 0:7    |
| 01        | 8:15   |
| 10        | 16:23  |
| 11        | 24:31  |

The level that the TouCAN will drive onto internal IRQ[7:0] signals is programmed in the three Interrupt Request Level (IRL) bits located in the interrupt configuration register. The two ILBS bits in the ICR register determine on which slot the TouCAN should drive its interrupt signal. Under the control of ILBS, each interrupt request level is driven during the time multiplexed bus during one of four different time slots, with eight levels communicated per time slot. No hardware priority is assigned to interrupts. Furthermore, if more than one source on a module requests an interrupt at the same level, the system software must assign a priority to each source requesting at that level. [Figure 16-7](#) displays the interrupt levels on IRQ with ILBS.

Figure 16-7. Interrupt Levels on IRQ with ILBS

# 16.7 Programming Model

Table 16-10 shows the TouCAN address map. The lowercase “x” appended to each register name represents “A”, “B” or “C” for the TouCAN\_A, TouCAN\_B, or TouCAN\_C module, respectively. Refer to Figure 1-4 to locate each TouCAN module in the MPC561/MPC563 address map.

The column labeled “Access” indicates the privilege level at which the CPU must be operating to access the register. A designation of “S” indicates that supervisor mode is required. A designation of “S/U” indicates that the register can be programmed for either supervisor mode access or unrestricted access.

The address space for each TouCAN module is split, with 128 bytes starting at the base address, and an extra 256 bytes starting at the base address +128. The upper 256 are fully used for the message buffer structures. Of the lower 128 bytes, some are not used. Registers with bits marked as “reserved” should always be written as logic 0.

Typically, the TouCAN control registers are programmed during system initialization, before the TouCAN becomes synchronized with the CAN bus. The configuration registers can be changed after synchronization by halting the TouCAN module. This is done by setting the HALT bit in the TouCAN module configuration register (CANMCR). The TouCAN responds by asserting CANMCR[NOTRDY]. Additionally, the control registers can be modified while the MCU is in background debug mode.

## NOTE

The TouCAN has no hard-wired protection against invalid bit/field programming within its registers. Specifically, no protection is provided if the programming does not meet CAN protocol requirements.

Table 16-11. CANMCR Bit Descriptions

| Bits | Name    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|------|---------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | STOP    | Low-power stop mode enable. The STOP bit may only be set by the CPU. It may be cleared either by the CPU or by the TouCAN, if the SELF WAKE bit is set.<br>Before asserting the STOP Mode, the CPU should disable all interrupts in the TOUCAN, otherwise it may be interrupted while in STOP mode upon a non wake-up condition.<br>WAKE-INT can still be enabled by setting WAKEMSK.<br>0 Enable TouCAN clocks<br>1 Disable TouCAN clocks                                                                                                                           |
| 1    | FRZ     | FREEZE assertion response. When FRZ = 1, the TouCAN can enter debug mode when the IMB3 FREEZE line is asserted or the HALT bit is set. Clearing this bit field causes the TouCAN to exit debug mode. Refer to <a href="#">Section 16.5.1, “Debug Mode”</a> for more information.<br>0 TouCAN ignores the IMB3 FREEZE signal and the HALT bit in the module configuration register.<br>1 TouCAN module enabled to enter debug mode.                                                                                                                                   |
| 2    | —       | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 3    | HALT    | Halt TouCAN S-Clock. Setting the HALT bit has the same effect as assertion of the IMB3 FREEZE signal on the TouCAN without requiring that FREEZE be asserted. This bit is set to one after reset. It should be cleared after initializing the message buffers and control registers. TouCAN message buffer receive and transmit functions are inactive until this bit is cleared.<br>When HALT is set, write access to certain registers and bits that are normally read-only is allowed.<br>0 The TouCAN operates normally<br>1 TouCAN enters debug mode if FRZ = 1 |
| 4    | NOTRDY  | TouCAN not ready. This bit indicates that the TouCAN is either in low-power stop mode or debug mode. This bit is read-only and is set only when the TouCAN enters low-power stop mode or debug mode. It is cleared once the TouCAN exits either mode, either by synchronization to the CAN bus or by the self wake mechanism.<br>0 TouCAN has exited low-power stop mode or debug mode.<br>1 TouCAN is in low-power stop mode or debug mode.                                                                                                                         |
| 5    | WAKEMSK | Wakeup interrupt mask. The WAKEMSK bit enables wake-up interrupt requests.<br>0 Wake up interrupt is disabled<br>1 Wake up interrupt is enabled                                                                                                                                                                                                                                                                                                                                                                                                                      |

**Table 16-11. CANMCR Bit Descriptions (continued)**

| Bits  | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-------|----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 6     | SOFRST   | <p>Soft reset. When this bit is asserted, the TouCAN resets its internal state machines (sequencer, error counters, error flags, and timer) and the host interface registers (CANMCR, CANICR, CANTCR, IMASK, and IFLAG).</p> <p>The configuration registers that control the interface with the CAN bus are not changed (CANCTRL[0:2] and PRESDIV). Message buffers and receive message masks are also not changed. This allows SOFRST to be used as a debug feature while the system is running. Setting SOFRST also clears the STOP bit in CANMCR.</p> <p>After setting SOFRST, allow one complete bus cycle to elapse for the internal TouCAN circuitry to completely reset before executing another access to CANMCR.</p> <p>The TouCAN clears this bit once the internal reset cycle is completed.</p> <p>0 Soft reset cycle completed<br/>1 Soft reset cycle initiated</p> |
| 7     | FRZACK   | <p>TouCAN disable. When the TouCAN enters debug mode, it sets the FRZACK bit. This bit should be polled to determine if the TouCAN has entered debug mode. When debug mode is exited, this bit is negated once the TouCAN prescaler is enabled. This is a read-only bit.</p> <p>0 The TouCAN has exited debug mode and the prescaler is enabled<br/>1 The TouCAN has entered debug mode, and the prescaler is disabled</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 8     | SUPV     | <p>Supervisor/user data space. The SUPV bit places the TouCAN registers in either supervisor or user data space.</p> <p>0 Registers with access controlled by the SUPV bit are accessible in either user or supervisor privilege mode<br/>1 Registers with access controlled by the SUPV bit are restricted to supervisor mode</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 9     | SELFWAKE | <p>Self wake enable. This bit allows the TouCAN to wake up when bus activity is detected after the STOP bit is set. If this bit is set when the TouCAN enters low-power stop mode, the TouCAN will monitor the bus for a recessive to dominant transition. If a recessive to dominant transition is detected, the TouCAN immediately clears the STOP bit and restarts its clocks. If a write to CANMCR with SELFWAKE set occurs at the same time a recessive-to-dominant edge appears on the CAN bus, the bit will not be set, and the module clocks will not stop. The user should verify that this bit has been set by reading CANMCR. Refer to <a href="#">Section 16.5.2, “Low-Power Stop Mode”</a> for more information on entry into and exit from low-power stop mode.</p> <p>0 Self wake disabled<br/>1 Self wake enabled</p>                                            |
| 10    | APS      | <p>Auto power save. The APS bit allows the TouCAN to automatically shut off its clocks to save power when it has no process to execute, and to automatically restart these clocks when it has a task to execute without any CPU intervention.</p> <p>0 Auto power save mode disabled; clocks run normally<br/>1 Auto power save mode enabled; clocks stop and restart as needed</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 11    | STOPACK  | <p>Stop acknowledge. When the TouCAN is placed in low-power stop mode and shuts down its clocks, it sets the STOPACK bit. This bit should be polled to determine if the TouCAN has entered low-power stop mode. When the TouCAN exits low-power stop mode, the STOPACK bit is cleared once the TouCAN's clocks are running.</p> <p>0 The TouCAN is not in low-power stop mode and its clocks are running<br/>1 The TouCAN has entered low-power stop mode and its clocks are stopped</p>                                                                                                                                                                                                                                                                                                                                                                                         |
| 12:15 | —        | Reserved. These bits are used for the IARB (interrupt arbitration ID) field in TouCAN implementations that use hardware interrupt arbitration.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

### 16.7.2 TouCAN Test Configuration Register

CANTCR — TouCAN Test Configuration Register 0x30 7082, 0x30 7482, 0x30 7882

This register is used for factory test only.

### 16.7.3 TouCAN Interrupt Configuration Register (CANICR)

|        |                                                                  |   |   |   |   |     |   |   |      |   |         |    |    |    |    |     |

| Addr   | 0x30 7086 (CANCTRL0_A); 0x30 7486 (CANCTRL0_B); 0x30 7886 (CANCTRL0_C) |        |   |   |        |   |        |   |          |   |    |    |    |    |     |    |

Figure 16-11. Control Register 0 (CANCTRL0)

**Table 16-13. CANCTRL0 Bit Descriptions**

| Bits | Name     | Description                                                                                                                                         |
|------|----------|-----------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | BOFFMSK  | Bus off interrupt mask. The BOFF MASK bit provides a mask for the bus off interrupt.<br>0 Bus off interrupt disabled<br>1 Bus off interrupt enabled |
| 1    | ERRMSK   | Error interrupt mask. The ERRMSK bit provides a mask for the error interrupt.<br>0 Error interrupt disabled<br>1 Error interrupt enabled            |
| 2:3  | —        | Reserved                                                                                                                                            |
| 4:5  | RXMODE   | Receive signal configuration control. These bits control the configuration of the CNRX0 signals. Refer to <a href="#">Table 16-14</a> .             |
| 6:7  | TXMODE   | Transmit signal configuration control. This bit field controls the configuration of the CNTX0 signals. Refer to <a href="#">Table 16-15</a> .       |
| 8:15 | CANCTRL1 | See <a href="#">Table 16-16</a> and <a href="#">Section 16.7.5, “Control Register 1 (CANCTRL1)”</a> .                                               |

**Table 16-14. Rx MODE[1:0] Configuration**

| Signal | RX1 | RX0 | Receive Signal Configuration                                                                        |
|--------|-----|-----|-----------------------------------------------------------------------------------------------------|
| CNRX0  | X   | 0   | 0 CNRX0 signal is interpreted as a dominant bit<br>1 CNRX0 signal is interpreted as a recessive bit |
|        | X   | 1   | 0 CNRX0 signal is interpreted as a recessive bit<br>1 CNRX0 signal is interpreted as a dominant bit |

**Table 16-15. Transmit Signal Configuration**

| TXMODE[1:0] | TransmitSignal Configuration                                               |
|-------------|----------------------------------------------------------------------------|
| 00          | Full CMOS <sup>1</sup> ; positive polarity (CNTX0 = 0 is a dominant level) |
| 01          | Full CMOS <sup>1</sup> ; negative polarity (CNTX0 = 1 is a dominant level) |
| 1X          | Open drain <sup>2</sup> ; positive polarity                                |

<sup>1</sup> Full CMOS drive indicates that both dominant and recessive levels are driven by the chip.

<sup>2</sup> Open drain drive indicates that only a dominant level is driven by the chip. During a recessive level, the CNTX0 signal is disabled (three stated), and the electrical level is achieved by external pull-up/pull-down devices. The assertion of both Tx mode bits causes the polarity inversion to be cancelled (open drain mode forces the polarity to be positive).

## 16.7.5 Control Register 1 (CANCTRL1)

|        |                                                                        |   |   |   |   |   |   |   |      |   |       |      |    |         |    |     |

| Bits  | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-------|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7   | CANCTRL0 | See <a href="#">Table 16-13</a>                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 8     | SAMP     | Sampling mode. The SAMP bit determines whether the TouCAN module will sample each received bit one time or three times to determine its value.<br>0 One sample, taken at the end of phase buffer segment one, is used to determine the value of the received bit.<br>1 Three samples are used to determine the value of the received bit. The samples are taken at the normal sample point and at the two preceding periods of the S-clock.                                                                  |
| 9     | —        | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 10    | TSYNC    | Timer synchronize mode. The TSYNC bit enables the mechanism that resets the free-running timer each time a message is received in message buffer zero. This feature provides the means to synchronize multiple TouCAN stations with a special “SYNC” message (global network time).<br>0 Timer synchronization disabled.<br>1 Timer synchronization enabled.<br>Note: there can be a bit clock skew of four to five counts between different TouCAN modules that are using this feature on the same network. |
| 11    | LBUF     | Lowest buffer transmitted first. The LBUF bit defines the transmit-first scheme.<br>0 Message buffer with lowest ID is transmitted first.<br>1 Lowest numbered buffer is transmitted first.                                                                                                                                                                                                                                                                                                                  |
| 12    | —        | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 13:15 | PROPSEG  | Propagation segment time. PROPSEG defines the length of the propagation segment in the bit time. The valid programmed values are zero to seven. The propagation segment time is calculated as follows:<br>Propagation Segment Time = (PROPSEG + 1) Time Quanta<br>where<br>1 Time Quantum = 1 Serial Clock (S-Clock) Period                                                                                                                                                                                  |

### 16.7.6 Prescaler Divide Register (PRES DIV)

**Figure 16-13. Prescaler Divide Register**

**Table 16-17. PRES DIV Bit Descriptions**

| Bits | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------|----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7  | PRES DIV | <p>Prescaler divide factor. PRES DIV determines the ratio between the system clock frequency and the serial clock (S-clock). The S-clock is determined by the following calculation:</p> $\text{S-clock} = \frac{f_{\text{SYS}}}{\text{PRES DIV} + 1}$ <p style="text-align: right;"><b>Eqn. 16-1</b></p> <p>The reset value of PRES DIV is 0x00, which forces the S-clock to default to the same frequency as the system clock. The valid programmed values are 0 through 255.</p> |
| 8:15 | CANCTRL2 | See <a href="#">Table 16-18</a> .                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

|------|-------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:15 | TIMER | <p>The free running timer counter can be read and written by the CPU. The timer starts from zero after reset, counts linearly to 0xFFFF, and wraps around.</p> <p>The timer is clocked by the TouCAN bit-clock. During a message, it increments by one for each bit that is received or transmitted. When there is no message on the bus, it increments at the nominal bit rate.</p> <p>The timer value is captured at the beginning of the identifier field of any frame on the CAN bus. The captured value is written into the “time stamp” entry in a message buffer after a successful reception or transmission of a message.</p> |

|------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:31 | MIDx | <p>The receive global mask registers use four bytes. The mask bits are applied to all receive-identifiers, excluding receive-buffers 14 and 15, which have their own specific mask registers.</p> <p>Base ID mask bits MID[28:18] are used to mask standard or extended format frames.</p> <p>Extended ID bits MID[17:0] are used to mask only extended format frames.</p> <p>The RTR/SRR bit of a received frame is never compared to the corresponding bit in the message buffer ID field. However, remote request frames (RTR = 1) once received, are never stored into the message buffers. RTR mask bit locations in the mask registers (bits 11 and 31) are always zero, regardless of any write to these bits.</p> <p>The IDE bit of a received frame is always compared to determine if the message contains a standard or extended identifier. Its location in the mask registers (bit 12) is always one, regardless of any write to this bit.</p> |

### 16.7.10 Receive Buffer 14 Mask Registers (RX14MSKHI, RX14MSKLO)

The receive buffer 14 mask registers have the same structure as the receive global mask registers and are used to mask buffer 14.

### 16.7.11 Receive Buffer 15 Mask Registers (RX15MSKHI, RX15MSKLO)

The receive buffer 15 mask registers have the same structure as the receive global mask registers and are used to mask buffer 15.

[illegible]

### Figure 16-19. Error and Status Register (ESTAT)

This register reflects various error conditions, general status, and has the enable bits for three of the TouCAN interrupt sources. The reported error conditions are those which have occurred since the last time the register was read. A read clears these bits to zero.

**Table 16-23. ESTAT Bit Descriptions**

| Bits  | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|-------|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:1   | BITERR   | Transmit bit error. The BITERR[1:0] field is used to indicate when a transmit bit error occurs. Refer to <a href="#">Table 16-24</a> .<br>NOTE: The transmit bit error field is not modified during the arbitration field or the ACK slot bit time of a message, or by a transmitter that detects dominant bits while sending a passive error frame.                                                                                                                                                                     |
| 2     | ACKERR   | Acknowledge error. The ACKERR bit indicates whether an acknowledgment has been correctly received for a transmitted message.<br>0 No ACK error was detected since the last read of this register<br>1 An ACK error was detected since the last read of this register                                                                                                                                                                                                                                                     |
| 3     | CRCERR   | Cyclic redundancy check error. The CRCERR bit indicates whether or not the CRC of the last transmitted or received message was valid.<br>0 No CRC error was detected since the last read of this register<br>1 A CRC error was detected since the last read of this register                                                                                                                                                                                                                                             |
| 4     | FORMERR  | Message format error. The FORMERR bit indicates whether or not the message format of the last transmitted or received message was correct.<br>0 No format error was detected since the last read of this register<br>1 A format error was detected since the last read of this register                                                                                                                                                                                                                                  |
| 5     | STUFFERR | Bit stuff error. The STUFFERR bit indicates whether or not the bit stuffing that occurred in the last transmitted or received message was correct.<br>0 No bit stuffing error was detected since the last read of this register<br>1 A bit stuffing error was detected since the last read of this register                                                                                                                                                                                                              |
| 6     | TXWARN   | Transmit error status flag. The TXWARN status flag reflects the status of the TouCAN transmit error counter.<br>0 Transmit error counter < 96<br>1 Transmit error counter ≥ 96                                                                                                                                                                                                                                                                                                                                           |
| 7     | RXWARN   | Receiver error status flag. The RXWARN status flag reflects the status of the TouCAN receive error counter.<br>0 Receive error counter < 96<br>1 Receive error counter ≥ 96                                                                                                                                                                                                                                                                                                                                              |
| 8     | IDLE     | Idle status. The IDLE bit indicates when there is activity on the CAN bus.<br>0 The CAN bus is not idle<br>1 The CAN bus is idle                                                                                                                                                                                                                                                                                                                                                                                         |
| 9     | TX/RX    | Transmit/receive status. The TX/RX bit indicates when the TouCAN module is transmitting or receiving a message. TX/RX has no meaning when IDLE = 1.<br>0 The TouCAN is receiving a message if IDLE = 0<br>1 The TouCAN is transmitting a message if IDLE = 0                                                                                                                                                                                                                                                             |
| 10:11 | FCS      | Fault confinement state. The FCS[1:0] field describes the state of the TouCAN. Refer to <a href="#">Table 16-25</a> .<br>If the SOFTRST bit in CANMCR is asserted while the TouCAN is in the bus off state, the error and status register is reset, including FCS[1:0]. However, as soon as the TouCAN exits reset, FCS[1:0] bits will again reflect the bus off state. Refer to <a href="#">Section 16.3.4, “Error Counters”</a> for more information on entry into and exit from the various fault confinement states. |
| 12    | —        | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

**Table 16-23. ESTAT Bit Descriptions (continued)**

| Bits | Name    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|------|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 13   | BOFFINT | Bus off interrupt. The BOFFINT bit is used to request an interrupt when the TouCAN enters the bus off state.<br>0 No bus off interrupt requested<br>1 When the TouCAN state changes to bus off, this bit is set, and if the BOFFMSK bit in CANCTRL0 is set, an interrupt request is generated. This interrupt is not requested after reset.                                                                                                                           |
| 14   | ERRINT  | Error Interrupt. The ERRINT bit is used to request an interrupt when the TouCAN detects a transmit or receive error.<br>0 No error interrupt request<br>1 If an event which causes one of the error bits in the error and status register to be set occurs, the error interrupt bit is set. If the ERRMSK bit in CANCTRL0 is set, an interrupt request is generated.<br>To clear this bit, first read it as a one, then write as a zero. Writing a one has no effect. |
| 15   | WAKEINT | Wake interrupt. The WAKEINT bit indicates that bus activity has been detected while the TouCAN module is in low-power stop mode.<br>0 No wake interrupt requested<br>1 When the TouCAN is in low-power stop mode and a recessive to dominant transition is detected on the CAN bus, this bit is set. If the WAKEMSK bit is set in CANMCR, an interrupt request is generated.                                                                                          |

**Table 16-24. Transmit Bit Error Status**

| BITERR[1:0] | Bit Error Status                                            |
|-------------|-------------------------------------------------------------|
| 00          | No transmit bit error                                       |
| 01          | At least one bit sent as dominant was received as recessive |
| 10          | At least one bit sent as recessive was received as dominant |
| 11          | Not used                                                    |

**Table 16-25. Fault Confinement State Encoding**

| FCS[1:0] | Bus State     |
|----------|---------------|
| 00       | Error active  |
| 01       | Error passive |
| 1X       | Bus off       |

### 16.7.13 Interrupt Mask Register (IMASK)

|        |                                                               |   |   |   |   |   |   |   |   |   |        |    |    |    |    |    |    |     |
|--------|---------------------------------------------------------------|---|---|---|---|---|---|---|---|---|--------|----|----|----|----|----|----|-----|
|        | MSB                                                           | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9      | 10 | 11 | 12 | 13 | 14 | 15 | LSB |
| Field  | IMASKH                                                        |   |   |   |   |   |   |   |   |   | IMASKL |    |    |    |    |    |    |     |
| SRESET | 0000_0000_0000_0000                                           |   |   |   |   |   |   |   |   |   |        |    |    |    |    |    |    |     |
| Addr   | 0x30 70A2 (IMASK_A); 0x30 74A2 (IMASK_B); 0x30 78A2 (IMASK_C) |   |   |   |   |   |   |   |   |   |        |    |    |    |    |    |    |     |

**Figure 16-20. Interrupt Mask Register (IMASK)**

**Table 16-26. IMASK Bit Descriptions**

| Bits         | Name              | Description                                                                                                                                                                                                                                                                                                                                                                                                                      |
|--------------|-------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7,<br>8:15 | IMASKH,<br>IMASKL | IMASK contains two 8-bit fields, IMASKH and IMASKL. IMASK can be accessed with a 16-bit read or write, and IMASKH and IMASKL can be accessed with byte reads or writes. IMASK contains one interrupt mask bit per buffer. It allows the CPU to designate which buffers will generate interrupts after successful transmission/reception. Setting a bit in IMASK enables interrupt requests for the corresponding message buffer. |

### 16.7.14 Interrupt Flag Register (IFLAG)

|                            |                                                               |   |   |   |   |   |   |   |   |        |   |    |    |    |    |    |    |     |
|----------------------------|---------------------------------------------------------------|---|---|---|---|---|---|---|---|--------|---|----|----|----|----|----|----|-----|
|                            | MSB                                                           | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8      | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |
| Field                      | IFLAGH                                                        |   |   |   |   |   |   |   |   | IFLAGL |   |    |    |    |    |    |    |     |
| $\overline{\text{SRESET}}$ | 0000_0000_0000_0000                                           |   |   |   |   |   |   |   |   |        |   |    |    |    |    |    |    |     |
| Addr                       | 0x30 70A4 (IFLAG_A); 0x30 74A4 (IFLAG_B); 0x30 78A4 (IFLAG_C) |   |   |   |   |   |   |   |   |        |   |    |    |    |    |    |    |     |

**Figure 16-21. Interrupt Flag Register (IFLAG)**
**Table 16-27. IFLAG Bit Descriptions**

| Bits         | Name              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------|-------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7,<br>8:15 | IFLAGH,<br>IFLAGL | IFLAG contains two 8-bit fields, IFLAGH and IFLAGL. IFLAG can be accessed with a 16-bit read or write, and IFLAGH and IFLAGL can be accessed with byte reads or writes. IFLAG contains one interrupt flag bit per buffer. Each successful transmission/reception sets the corresponding IFLAG bit and, if the corresponding IMASK bit is set, an interrupt request will be generated.<br>To clear an interrupt flag, first read the flag as a one, and then write it as a zero. Should a new flag setting event occur between the time that the CPU reads the flag as a one and writes the flag as a zero, the flag is not cleared. This register can be written to zeros only. |

### 16.7.15 Error Counters (RXECTR, TXECTR)

|                            |                                                                                             |   |   |   |   |   |   |   |   |        |   |    |    |    |    |    |    |     |
|----------------------------|---------------------------------------------------------------------------------------------|---|---|---|---|---|---|---|---|--------|---|----|----|----|----|----|----|-----|
|                            | MSB                                                                                         | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8      | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |

## Chapter 17

# Modular Input/Output Subsystem (MIOS14)

The modular I/O system (MIOS) consists of a library of flexible I/O and timer functions including I/O port, counters, input capture, output compare, pulse and period measurement, and PWM. Because the MIOS14 is composed of submodules, it is easily configurable for different kinds of applications.

The MIOS14 is composed of the following submodules:

- One MIOS14 bus interface submodule (MBISM)
- One MIOS14 counter prescaler submodule (MCPSM)
- Six MIOS14 modulus counter submodules (MMCSM)
- 10 MIOS14 double action submodules (MDASM)
- 12 MIOS14 pulse-width modulation submodules (MPWMSM)
- One MIOS14 16-bit parallel port I/O submodule (MPIOSM)
- Two interrupt request submodules (MIRSM)

### 17.1 Block Diagram

[Figure 17-1](#) is a block diagram of the MIOS14.

Figure 17-1. MPC561/MPC563 MIOS14 Block Diagram

## 17.2 MIOS14 Key Features

The basic features of the MIOS14 are as follows:

- Modular architecture at the silicon implementation level
- Disable capability in each submodule to allow power saving when its function is not needed
- Six 16-bit counter buses to allow action submodules to use counter data
- When not used for timing functions, every channel signal can be used as a port signal: I/O, output only or input only, depending on the channel function.
- Submodules' signal status bits reflect the status of the signal
- MIOS14 counter prescaler submodule (MCPSM):
  - Centralized counter clock generator
  - Programmable 4-bit modulus down-counter
  - Wide range of possible division ratios: 2 through 16
  - Count inhibit under software control
- MIOS14 modulus counter submodule (MMCSM):
  - Programmable 16-bit modulus up-counter with built-in programmable 8-bit prescaler clocked by MCPSM output.
  - Maximum increment frequency of the counter:
    - Clocked by the internal MCPSM output:  $f_{SYS} / 2$
    - Clocked by the external signal:  $f_{SYS} / 4$
  - Flag setting and possible interrupt generation on overflow of the up-counter
  - Time counter on internal clock with interrupt capability after a pre-determined time
  - Optional signal usable as an external event counter (pulse accumulator) with overflow and interrupt capability after a pre-determined number of external events.
  - Usable as a regular free-running up-counter
  - Capable of driving a dedicated 16-bit counter bus to provide timing information to action submodules (the value driven is the contents of the 16-bit up-counter register)
  - Optional signal to externally force a load to the counter with modulus value
- MIOS14 double action submodule (MDASM):
  - Versatile 16-bit dual action unit allowing two events to occur before software intervention is required
  - Six software selectable modes allowing the MDASM to perform pulse width and period measurements, PWM generation, single input capture and output compare operations as well as port functions
  - Software selection of one of the six possible 16-bit counter buses used for timing operations
  - Flag setting and possible interrupt generation after MDASM action completion
  - Software selection of output pulse polarity
  - Software selection of totem-pole or open-drain output
  - Software readable output signal status

- Possible use of signal as I/O port when MDASM function is not needed
- MIOS14 pulse width modulation submodule (MPWMSM):
  - Output pulse width modulated (PWM) signal generation with no software involvement
  - Built-in 8-bit programmable prescaler clocked by the MCPSM
  - PWM period and pulse width values provided by software:
    - Double-buffered for glitch-free period and pulse width changes
    - Two-cycle minimum output period/pulse-width increment (50 ns @ 40 MHz)
    - 50% duty-cycle output maximum frequency: 10 MHz
    - Up to 16 bits output pulse width resolution
    - Wide range of periods:
      - 16 bits of resolution: period range from 3.27 ms (with 50-ns steps) to 6.71 s (with 102.4  $\mu$ s steps)
      - Eight bits of resolution: period range from 12.8  $\mu$ s (with 50-ns steps) to 26.2 ms (with 102.4- $\mu$ s steps)
    - Wide range of frequencies:
      - Maximum output frequency at  $f_{SYS} = 40$  MHz with 16 bits of resolution and divide-by-2 prescaler selection: 305 Hz (3.27 ms)
      - Minimum output frequency at  $f_{SYS} = 40$  MHz with 16 bits of resolution and divide-by-4096 prescaler selection: 0.15 Hz (6.7 s)
      - Maximum output frequency at  $f_{SYS} = 40$  MHz with eight bits of resolution and divide-by-2 prescaler selection: 78125 Hz (12.8  $\mu$ s)
      - Minimum output frequency at  $f_{SYS} = 40$  MHz with 8 bits of resolution and divide-by-4096 prescaler selection: 38.14 Hz (8.2 ms)
  - Programmable duty cycle from 0% to 100%
  - Possible interrupt generation after every period
  - Software selectable output pulse polarity
  - Software readable output signal status
  - Possible use of signal as I/O port when PWM function is not needed
  - MIOS14 16-bit parallel port I/O submodule (MPIOSM):
    - Up to 16 parallel I/O signals per MPIOSM
    - Uses four 16-bit registers in the address space, one for data and one for direction and two reserved
    - Simple data direction register (DDR) concept for selection of signal direction

### 17.2.1 Submodule Numbering, Naming, and Addressing

A block is a group of four 16-bit registers. Each of the blocks within the MIOS14 addressing range is assigned a block number. The first block is located at the base address of the MIOS14. The blocks are numbered sequentially starting from 0.

Every submodule instantiation is also assigned a number. The number of a given submodule is the block number of the first block of this submodule.

A submodule is assigned a name made of its acronym followed by its submodule number. For example, if submodule number 18 were an MPWMSM, it would be named MPWMSM18.

This numbering convention does not apply to the MBISM, the MCPSM, and the MIRSMs. The MBISM and the MCPSM are unique in the MIOS14 and do not need a number. The MIRSMs are numbered incrementally starting from zero.

The MIOS14 base address is defined at the chip level and is referred to as the “MIOS14 base address.” The MIOS14 addressable range is four Kbytes.

The base address of a given implemented submodule within the MIOS14 is the sum of the base address of the MIOS14 and the submodule number multiplied by eight. Refer to [Table 17-1](#).

This does not apply to the MBISM, the MCPSM and the MIRSMs. For these submodules, refer to the MIOS14 memory map in [Figure 17-2](#).

## 17.2.2 Signal Naming Convention

In [Figure 17-2](#), MDASM signals have a prefix MDA, MPWMSM signals have a prefix of MPWM and the port signals have a prefix of MPIO. The modulus counter clock and load signals are multiplexed with MDASM signals.

The MIOS14 input and output signal names are composed of five fields according to the following convention:

- “M”
- <submodule short\_prefix>
- <submodule number>
- <signal attribute suffix> (optional)
- <bit number> (optional)

The signal prefix and suffix for the different MIOS14 submodules are as follows:

- MMCSM:
  - submodule short\_prefix: “MC”
  - signal attribute suffix: C for the clock signal
  - signal attribute suffix: L for the load signal
  - For example, an MMCSM placed as submodule number  $n$  would have its corresponding input clock pin named MMCnC and its input load pin named MMCnL. MMC6C is input on MDA11 and MMC22C is input on MDA13. The MMC6L is input on MDA12 and MMC22C is input on MDA14.
- MDASM:
  - submodule short\_prefix: “DA”
  - signal attribute suffix: none

- For example a MDASM placed as submodule number  $n$  would have its corresponding channel I/O signal named MDAn
- MPWMSM:
  - submodule short\_prefix: “PWM”
  - signal attribute suffix: none
  - For example a MPWMSM placed as submodule number  $n$  would have its corresponding channel I/O signal named MPWMn
- MPIOSM:
  - submodule short\_prefix: “PIO”
  - signal attribute suffix: B
  - For example a MPIOSM placed as submodule number  $n$  would have its corresponding I/O signals named MPIONB0 to MPIONB15 for bit-0 to bit-15, respectively.

In the MIOS14, some signals are multiplexed between submodules using the same signal names for the inputs and outputs which are connected as shown in [Table 17-1](#).

## 17.3 MIOS14 Configuration

The complete MIOS14 submodule and signal configuration is shown in [Table 17-1](#).

**Table 17-1. MIOS14 Configuration Description**

| Sub-Module Type | Block No. | Connected to:    |                  |                  |                  | MIRSM No. | MIRSM Bit Position | Base Address Offset | Signal Function | Input Signal Name | Output Signal Name | Alternate Signal Name |
|-----------------|-----------|------------------|------------------|------------------|------------------|-----------|--------------------|---------------------|-----------------|-------------------|--------------------|-----------------------|
|                 |           | CBA              | CBB              | CBC              | CBD              |           |                    |                     |                 |                   |                    |                       |
|                 |           | BSL0=0<br>BSL1=0 | BSL0=1<br>BSL1=0 | BSL0=0<br>BSL1=1 | BSL0=1<br>BSL1=1 |           |                    |                     |                 |                   |                    |                       |
| PWMSM           | 0         |                  |                  |                  |                  | 0         | 0                  | 0x30 6000           | PWM, I/O        | MPWM0             | MPWM0              | MDI1                  |
| PWMSM           | 1         |                  |                  |                  |                  | 0         | 1                  | 0x30 6008           | PWM, I/O        | MPWM1             | MPWM1              | MDO2                  |
| PWMSM           | 2         |                  |                  |                  |                  | 0         | 2                  | 0x30 6010           | PWM, I/O        | MPWM2             | MPWM2              | PPM_TX1               |
| PWMSM           | 3         |                  |                  |                  |                  | 0         | 3                  | 0x30 6018           | PWM, I/O        | MPWM3             | MPWM3              | PPM_RX1               |
| PWMSM           | 4         |                  |                  |                  |                  | 0         | 4                  | 0x30 6020           | PWM, I/O        | MPWM4             | MPWM4              | MDO6/<br>MPIO32B6     |
| PWMSM           | 5         |                  |                  |                  |                  | 0         | 5                  | 0x30 6028           | PWM, I/O        | MPWM5             | MPWM5              | MPIO32B7              |
| MMCSM           | 6         | CB6              |                  |                  |                  | 0         | 6                  | 0x30 6030           | Clock In        | MDA11             |                    |                       |
|                 |           |                  |                  |                  |                  |           |                    |                     | Load In         | MDA12             |                    |                       |
| MMCSM           | 7         |                  |                  | CB7              |                  | 0         | 7                  | 0x30 6038           | Clock In        | MDA30             |                    |                       |

Table 17-1. MIOS14 Configuration Description (continued)

| Sub-Module Type | Block No. | Connected to:    |                  |                  |                  | MIRSM No. | MIRSM Bit Position | Base Address Offset | Signal Function | Input Signal Name | Output Signal Name | Alternate Signal Name |

### 17.3.1 MIOS14 Signals

The MIOS14 requires 34 signals: 10 MDASM signals, 8 dedicated MPWMSM signals, 12 dedicated MPIOISM signals and 4 signals are shared between the MPWMSM and MPIOISM. The required signal function on shared signals is chosen using the PDMCR2 register in the USIU. The usage of all MIOS14 signals is shown in the block diagram of [Figure 17-1](#) and in the configuration description of [Table 17-1](#).

### 17.3.2 MIOS14 Bus System

The internal bus system within the MIOS14 is called the modular I/O bus (MIOB). The MIOB makes communications possible between any submodule and the IMB3 bus master through the MBISM.

The MIOB is divided into three dedicated buses:

- The read/write and control bus
- The request bus
- The counter bus set

### 17.3.3 Read/Write and Control Bus

The read/write and control bus (RWCB) allows read and write data transfers to and from any I/O submodule through the MBISM. It includes signals for data and addresses as well as control signals. The control signals allow 16-bit simple synchronous single master accesses and supports fast or slow master accesses.

### 17.3.4 Request Bus

The request bus (RQB) provides interrupt request signals along with I/O submodule identification and priority information to the MBISM.

#### NOTE

Some submodules do not generate interrupts and are therefore independent of the RQB.

### 17.3.5 Counter Bus Set

The 16-bit counter bus set (CBS) is a set of six 16-bit counter buses. The CBS makes it possible to transfer information between submodules. Typically, counter submodules drive the CBS, while action submodules process the data on these buses. Note, however, that some submodules are self-contained and therefore independent of the counter bus set.

## 17.4 MIOS14 Programming Model

The address space of the MIOS14 consist of 4 Kbytes starting at the base address of the module (0x306000). The overall address map organization is shown in [Figure 17-2](#).

All MIOS14 unimplemented locations within the addressable range, return a logic 0 when accessed. In addition, the internal  $\overline{\text{TEA}}$  (transfer error acknowledge) signal is asserted.

All unused bits within MIOS14 registers return a 0 when accessed.

### 17.4.1 Bus Error Support

A bus error signal is generated when access to an unimplemented or reserved 16-bit register is attempted, or when a privileged violation occurs. A bus error is generated under any of the following conditions:

- Attempted access to unimplemented 16-bit registers within the decoded register block boundary.
- Attempted user access to supervisor registers
- Attempted access to test registers when not in test mode
- Attempted write to read-only registers

## 17.4.2 Wait States

The MIOS14 does not generate wait states.

Figure 17-2. MIOS14 Memory Map

## 17.5 MIOS14 I/O Ports

Each signal of each submodule can be used as an input, output, or I/O port:

Table 17-2. MIOS14 I/O Ports

| Submodule | Number of Pins per Module | Type |
|-----------|---------------------------|------|
| MPIOSM    | 16                        | I/O  |
| MMCSM     | 2                         | I    |
| MDASM     | 1                         | I/O  |
| MPWMSM    | 1                         | I/O  |

## 17.6 MIOS14 Bus Interface Submodule (MBISM)

The MIOS14 bus interface submodule (MBISM) is used as an interface between the MIOB (modular I/O bus) and the IMB3. It allows the CPU to communicate with the MIOS14 submodules.

### 17.6.1 MIOS14 Bus Interface (MBISM) Registers

Table 17-3 is the address map for the MBISM submodule.

|           | MSB                                                  | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | LSB | 15 |

Figure 17-3. MBISM Registers

#### 17.6.1.1 MIOS14 Test and Signal Control Register (MIOS14TPCR)

This register is used for MIOS14 factory testing and to control the VF and VFLS Signal usage. Control of other multiplexed functions is in the PDMCR2 register.

Figure 17-4. Test and Signal Control Register (MIOS14TPCR)

Table 17-3. MIOS14TPCR Bit Descriptions

| Bits | Name | Description                                                                                                                                                                                                                       |
|------|------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | TEST | Test — This bit is used for MIOS14 factory testing and should always be programmed to a 0.                                                                                                                                        |
| 1:13 | —    | Reserved                                                                                                                                                                                                                          |
| 14   | VF   | VF Pin Multiplex — This bit controls the function of the VF pins (VF0/MPIO32B0, VF1/MPIO32B1, VF2/MPIO32B2)<br>0 = MIOS14 General-Purpose I/O is selected (MPIO32B0, MPIO32B1, MPIO32B2)<br>1 = VF function is selected (VF[0:2]) |
| 15   | VFLS | VFLS Pin Multiplex — This bit controls the function of the VFLS signals (VFLS0/MPIO32B3, VFLS1/MPIO32B4)<br>0 = MIOS14 General-Purpose I/O is selected (MPIO32B3, MPIO32B4)<br>1 = VFLS function is selected (VFLS[0:1])          |

### 17.6.1.2 MIOS14 Vector Register (MIOS14VECT)

This register is reserved and is shown for information purposes only.

Figure 17-5. Vector Register (MIOS14VECT)

### 17.6.1.3 MIOS14 Module and Version Number Register (MIOS14VNR)

This read-only register contains the hard-coded values of the module and version number.

Figure 17-6. MIOS14 Module/Version Number Register (MIOS14VNR)

<sup>1</sup> This field contains the revision level of the MIOS module and may change with different revisions of the device.

**Table 17-4. MIOS14VNR Bit Descriptions**

| Bits | Name | Description                                                        |
|------|------|--------------------------------------------------------------------|
| 0:7  | MN   | Module number = 0x0E on the MPC561/MPC563                          |
| 8:15 | VN   | Version number. May change with different revisions of the device. |

### 17.6.1.4 MIOS14 Module Configuration Register (MIOS14MCR)

The MIOS14MCR register is a collection of read/write stop, freeze, reset, and supervisor bits, as well as interrupt arbitration number bits. These bits are detailed in [Table 17-5](#).

**Figure 17-7. Module Configuration Register (MIOS14MCR)**
**Table 17-5. MIOS14MCR Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|------|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | STOP | Stop enable — The STOP bit, while asserted, activates the MIOB freeze signal regardless of the state of the IMB3 FREEZE signal. The MIOB freeze signal is further validated in some submodules with internal freeze enable bits in order for the submodule to be stopped. The MBISM continues to operate to allow the CPU access to the submodule's registers. The MIOB freeze signal remains active until reset or until the STOP bit is written to zero by the CPU (via the IMB3). The STOP bit is cleared by reset.<br>0 Allows MIOS14 operation.<br>1 Selectively stops MIOS14 operation.                                                                      |
| 1    | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 2    | FRZ  | Freeze enable — The FRZ bit, while asserted, activates the MIOB freeze signal only when the IMB3 FREEZE signal is active. The MIOB freeze signal is further validated in some submodules with internal freeze enable bits in order for the submodule to be frozen. The MBISM continues to operate to allow the CPU access to the submodule's registers. The MIOB freeze signal remains active until the FRZ bit is written to zero or the IMB3 FREEZE signal is negated. The FRZ bit is cleared by reset.<br>0 Ignores the FREEZE signal on the IMB3, allows MIOS14 operation.<br>1 Selectively stops MIOS14 operation when the FREEZE signal appears on the IMB3. |
| 3    | RST  | Module reset — The RST bit is always read as 0 and can be written to 1. When the RST bit is written to 1 operation of the MIOS14 completely stops and resets all the values in the submodule. This completely stops the operation of the MIOS14 and reset all the values in the submodules registers that are affected by reset. This bit provides a way of resetting the complete MIOS14 module regardless of the reset state of the CPU. The RST bit is cleared by reset.<br>0 Writing a 0 to RST has no effect.<br>1 Reset the MIOS14 submodules.                                                                                                               |
| 4:7  | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

**Table 17-5. MIOS14MCR Bit Descriptions (continued)**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                         |
|------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 8    | SUPV | Supervisor data space selector — The SUPV bit tells if the address space from 0x30 6000 to 0x30 67FF in the MIOS14 is accessed at the supervisor privilege level (See <a href="#">Figure 17-2</a> ). When cleared, these addresses are accessed at the unrestricted privilege level.<br>The SUPV bit is cleared by reset.<br>0 Unrestricted Data Space.<br>1 Supervisor Data Space. |
| 9:15 | —    | Reserved. These bits are used for the IARB (interrupt arbitration ID) field in MIOS14 implementations that use hardware interrupt arbitration. These bits are not used on MPC561/MPC563.                                                                                                                                                                                            |

## 17.7 MIOS14 Counter Prescaler Submodule (MCPSM)

The MIOS14 counter prescaler submodule (MCPSM) divides the MIOS14 clock ( $f_{SYS}$ ) to generate the counter clock. It is designed to provide all the submodules with the same division of the main MIOS14 clock (division of  $f_{SYS}$ ). It uses a 4-bit modulus counter. The clock signal is prescaled by loading the value of the clock prescaler register into the prescaler counter every time it overflows. This allows all prescaling factors between 2 and 16. Counting is enabled by asserting MCPSMSCR[PREN]. The counter can be stopped at any time by negating this bit, thereby stopping all submodules using the output of the MCPSM (counter clock). A block diagram of the MCPSM is given in [Figure 17-8](#).

The following sections describe the MCPSM in detail.

**Figure 17-8. MCPSM Block Diagram**

### 17.7.1 MCPSM Features

- Centralized counter clock generator

- Programmable 4-bit modulus down-counter
- Wide range of possible division ratios: 2 through 16
- Count inhibit under software control

### 17.7.1.1 MCPSM Signal Functions

The MCPSM has no associated external signals.

### 17.7.1.2 Modular I/O Bus (MIOB) Interface

- The MCPSM is connected to all the signals in the read/write and control bus, to allow data transfer from and to the MCPSM registers, and to control the MCPSM in the different possible situations.
- The MIOB14 counter prescaler submodule does not use any 16-bit counter bus.
- The MIOB14 counter prescaler submodule does not use the request bus.

## 17.7.2 Effect of RESET on MCPSM

When the RESET signal is asserted, all the bits in the MCPSM status and control register are cleared.

### NOTE

The MCPSM is still disabled after the RESET signal is negated and counting must be explicitly enabled by asserting MCPSMSCR[PREN].

## 17.7.3 MCPSM Registers

The privilege level to access to the MCPSM registers is supervisor only.

### 17.7.3.1 MCPSM Registers Organization

Table 17-6. MCPSM Register Address Map

| Bits  | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-------|----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0     | PREN     | Prescaler enable bit — This active high read/write control bit enables the MCPSM counter. The PREN bit is cleared by reset.<br>0 MCPSM counter disabled.<br>1 MCPSM counter enabled.                                                                                                                                                                                                                                                                                                                                                                                             |
| 1     | FREN     | Freeze bit — This active high read/write control bit when set make possible a freeze of the MCPSM counter if the MIOB freeze line is activated. <b>NOTE:</b> This line is active when MIOS14MCR[STOP] is set or when MIOS14MCR[FREN] and the IMB3 FREEZE line are set. When the MCPSM is frozen, it stops counting. Then when the FREN bit is reset or when the freeze condition on the MIOB is negated, the counter restarts from where it was before freeze. The FREN bit is cleared by reset.<br>0 MCPSM counter not frozen.<br>1 MCPSM counter frozen if MIOB freeze active. |
| 2:11  | —        | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 12:15 | PSL[3:0] | Clock prescaler — This 4-bit read/write data register stores the modulus value for loading into the clock prescaler. The new value is loaded into the counter on the next time the counter equals one or when disabled (PREN =0).                                                                                                                                                                                                                                                                                                                                                |

**Table 17-8. Clock Prescaler Setting**

| PSL[3:0] Value |        | Divide Ratio            |
|----------------|--------|-------------------------|
| Hex            | Binary |                         |
| 0x0            | 0b0000 | 16                      |
| 0x1            | 0b0001 | No counter clock output |
| 0x2            | 0b0010 | 2                       |
| 0x3            | 0b0011 | 3                       |
| ...            | ...    | ...                     |
| 0xE            | 0b1110 | 14                      |
| 0xF            | 0b1111 | 15                      |

#### NOTE

If the binary value 0b0001 is entered in PSL[3:0], the output signal is stuck at zero, no clock is output.

## 17.8 MIOS14 Modulus Counter Submodule (MMCSM)

The MMCSM is a versatile counter submodule capable of performing complex counting and timing functions, including modulus counting, in a wide range of applications. The MMCSM may also be configured as an event counter, allowing the overflow flag to be set after a predefined number of events (internal clocks or external events), or as a time source for other submodules.

### NOTE

The MMCSM can also operate as a free running counter by loading the modulus value of zero.

The main components of the MMCSM are an 8-bit prescaler counter, an 8-bit prescaler register, a 16-bit up-counter register, a 16-bit modulus latch register, counter loading and interrupt flag generation logic.

The contents of the modulus latch register is transferred to the counter under the following three conditions:

1. When an overflow occurs
2. When an appropriate transition occurs on the external load signal
3. When the program writes to the counter register. In this case, the value is first written into the modulus register and immediately transferred to the counter.

Software can also write a value to the modulus register for later loading into the counter with one of the two first criteria.

A software control register selects whether the clock input to the counter is one of the prescaler outputs or the corresponding input signal. The polarity of the external input signal is also programmable.

The following sections describe the MMCSM in detail. A block diagram of the MMCSM is shown in [Figure 17-10](#).

Figure 17-10. MMCSM Block Diagram

Figure 17-11. MMCSM Modulus Up-Counter

### 17.8.1 MMCSM Features

- Programmable 16-bit modulus up-counter with a built-in programmable 8-bit prescaler clocked by MCPSM
- Maximum increment frequency of the counter:
  - clocked by the internal MCPSM output:  $f_{SYS} / 2$
  - clocked by the external signal:  $f_{SYS} / 4$
- Flag setting and possible interrupt generation on overflow of the up-counter register

- Time counter on internal clock with interrupt capability after a pre-determined time
- External event counter (pulse accumulator) with overflow and interrupt capability after a pre-determined number of external events
- Usable as a regular free-running up-counter
- Capable of driving a dedicated 16-bit counter bus to provide timing information to action submodules (the value driven is the contents of the 16-bit up-counter register)
- Optional signal for counting external events
- Optional signal to externally force a load of the modulus counter

### 17.8.1.1 MMCSM Signal Functions

The MMCSM has two dedicated external signals.

An external modulus load signal (MMCnL) allows the modulus value stored in the modulus latch register (MMCSMML) to be loaded into the up-counter register (MMCSMCNT) at any time. Both rising and falling edges of the load signal may be used, according to the EDGE<sub>P</sub> and EDGE<sub>N</sub> bit settings in the MMCSMSCR.

An external event clock signal (MMCnC) can be selected as the clock source for the up-counter register (MMCSMCNT) by setting the appropriate value in the CLS bit field of the status/control register (MMCSMSCR). Either rising or falling edge may be used according to the setting of these bits.

When the external clock source is selected, the MMCSM is in the event counter mode. The counter can simply counts the number of events occurring on the input signal. Alternatively, the MMCSM can be programmed to generate an interrupt when a predefined number of events have been counted; this is done by presetting the counter with the two's complement value of the desired number of events.

### 17.8.2 MMCSM Prescaler

The built-in prescaler consists of an 8-bit modulus counter, clocked by the MCPSM output. It is loaded with an 8-bit value every time the counter overflows or whenever the prescaler output is selected as the clock source. This 8-bit value is stored in the MMCSMSCR[CP]. The prescaler overflow signal is used to clock the MMCSM up-counter. This allows the MMCSMCNT to be incremented at the MCPSM output frequency divided by a value between 1 and 256.

### 17.8.3 Modular I/O Bus (MIOB) Interface

- The MMCSM is connected to all the signals in the read/write and control bus, to allow data transfer from and to the MMCSM registers, and to control the MMCSM in the different possible situations.
- The MMCSM drives a dedicated 16-bit counter bus with the value currently in the up-counter register
- The MMCSM uses the request bus to transmit the FLAG line to the interrupt request submodule (MIRSM). A flag is set when an overflow has occurred in the up-counter register.

## 17.8.4 Effect of RESET on MMCSM

When the RESET signal is asserted, only the FREN, EDGP, EDGN, and CLS bits in the MMCSMSCR are cleared. The clock prescaler CP, PINC, and PINL bits in the same register are not cleared.

- The PINC and PINL bits in the MMCSMSCR always reflect the state of the appropriate external pins.
- The MMCSM is disabled after reset and must be explicitly enabled by selecting a clock source using the CLS bits.

The MMCSMCNT and the MMCSMML, together with the clock prescaler register bits, must be initialized by software, because they are undefined after a hardware reset. A modulus value must be written to the MMCSMCNT (which also writes into the MMCSMML) before the MMCSMSCR is written to. The latter access initializes the clock prescaler.

## 17.8.5 MMCSM Registers

The privilege level to access to the MMCSM registers depends on the MIOS14MCR SUPV bit. The privilege level is unrestricted after  $\overline{\text{SRESET}}$  and can be changed to supervisor by software.

### 17.8.5.1 MMCSM Register Organization

**Table 17-9. MMCSM Address Map**

| Address       | Register                                                                                                                                                        |

### 17.8.5.2 MMCSM Up-Counter Register (MMCSMCNT)

Figure 17-12. MMCSM Up-Counter Register (MMCSMCNT)

Table 17-10. MMCSMCNT Bit Descriptions

| Bits | Name | Description                                                                                                                                                                                                                                  |
|------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:15 | CNT  | Counter value — These bits are read/write data bits representing the 16-bit value of the up-counter. It contains the value that is driven onto the 16-bit counter bus.<br><b>Note:</b> Writing to MMCSMCNT simultaneously writes to MMCSMML. |

### 17.8.5.3 MMCSM Modulus Latch Register (MMCSMML)

|        |                                                                  |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|--------|------------------------------------------------------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|
|        | MSB                                                              | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |
| Field  | ML                                                               |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
| SRESET | Undefined                                                        |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
| Addr   | 0x30 6032, 0x30 603A, 0x30 6042, 0x30 60B2, 0x30 60BA, 0x30 60C2 |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

**Figure 17-13. MMCSM Modulus Latch Register (MMCSMML)**

**Table 17-11. MMCSMML Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                             |
|------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:15 | ML   | Modulus latches — These bits are read/write data bits containing the 16-bit modulus value to be loaded into the up-counter.<br>The value loaded in this register must be the one's complement of the desired modulus count. The up-counter increments from this one's complement value up to 0xFFFF to get the correct number of steps before an overflow is generated to reload the modulus value into the up-counter. |

### 17.8.5.4 MMCSM Status/Control Register (MMCSMSCRD) (Duplicated)

The MMCSMSCRD and the MMCSMSCR are the same registers accessed at two different addresses. Reading or writing to one of these two addresses has exactly the same effect.

The duplication of the SCR register allows coherent 32-bit accesses when using a RCPU.

#### WARNING

The user should not write directly to the address of the MMCSMSCRD. This register's address may be reserved for future use and should not be accessed by the software to ensure future software compatibility.

### 17.8.5.5 MMCSM Status/Control Register (MMCSMSCR)

The status/control register (SCR) is a collection of read-only signal status bits, read/write control bits and an 8-bit read/write data register, as detailed below.

|        |                                                                  |      |      |      |      |     |   |   |    |   |    |    |    |    |     |    |
|--------|------------------------------------------------------------------|------|------|------|------|-----|---|---|----|---|----|----|----|----|-----|----|
|        | MSB                                                              |      |      |      |      |     |   |   |    |   |    |    |    |    | LSB |    |

**Figure 17-14. MMCSM Status/Control Register (MMCSMSCR)**

**Table 17-12. MMCSMSCR Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|------|------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | PINC | Clock input signal status bit — This read-only status bit reflects the logic state of the clock input signal MMCnC (MDA11, MDA13, MDA27, MDA30, PWM16, and PWM18).                                                                                                                                                                                                                                                                                                     |
| 1    | PINL | Modulus load input signal status bit — This read-only status bit reflects the logic state of the modulus load signal MMCnL (MDA12, MDA14, MDA28, MDA31, PWM17, and PWM19).                                                                                                                                                                                                                                                                                             |
| 2    | FREN | Freeze enable — This active high read/write control bit enables the MMCSM to recognize the MIOB freeze signal.                                                                                                                                                                                                                                                                                                                                                         |
| 3    | EDGN | Modulus load falling-edge sensitivity — This active high read/write control bit sets falling-edge sensitivity for the MMCnL signal, such that a high-to-low transition causes a load of the MMCSMCNT.                                                                                                                                                                                                                                                                  |
| 4    | EDGP | Modulus load rising-edge sensitivity<br>This active high read/write control bit sets rising-edge sensitivity for the MMCnL signal, such that a low-to-high transition causes a load of the MMCSMCNT.<br>See <a href="#">Table 17-13</a> for details about edge sensitivity.                                                                                                                                                                                            |
| 5:6  | CLS  | Clock select — These read/write control bits select the clock source for the modulus counter. Either the rising edge or falling edge of the clock signal on the MMCnC signal may be selected, as well as, the internal MMCSM prescaler output or disable mode (no clock source). See <a href="#">Table 17-14</a> for details about the clock selection.                                                                                                                |
| 7    | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 8:15 | CP   | Clock prescaler — This 8-bit data field is also accessible as an 8-bit data register. It stores the two's complement of the modulus value to be loaded into the built-in 8-bit clock prescaler. The new value is loaded into the prescaler counter on the next counter overflow, or upon setting the CLS1 — CLS0 bits for selecting the clock prescaler as the clock source.<br><a href="#">Table 17-15</a> gives the clock divide ratio according to the value of CP. |

**Table 17-13. MMCSMCNT Edge Sensitivity**

| EDGN | EDGP | Edge Sensitivity                          |
|------|------|-------------------------------------------|

## 17.9 MIOS14 Double Action Submodule (MDASM)

The MIOS14 double action submodule (MDASM) is a function included in the MIOS14 library. It is a versatile 16-bit dual action submodule capable of performing two event operations before software intervention is required. It can perform two event operations such as PWM generation and measurement, input capture, output compare, etc.

The MDASM is composed of two timing channels (A and B), an output flip-flop, an input edge detector and some control logic. All control and status bits are contained in the MDASM status and control register.

The following sections describe the MDASM in detail. A block diagram of the MDASM is shown in [Figure 17-15](#).

Figure 17-15. MDASM Block Diagram

### 17.9.1 MDASM Features

- Versatile 16-bit dual action unit allowing up to two events to occur before software intervention is required
- Six software selectable modes allowing the MDASM to perform pulse width and period measurements, PWM generation, single input capture and output compare operations as well as port functions
- Software selection of one of the four possible 16-bit counter buses used for timing operations
- Flag setting and possible interrupt generation after MDASM action completion
- Software selection of output pulse polarity
- Software selection of totem-pole or open-drain output
- Software readable output signal status

### 17.9.1.1 MDASM Signal Functions

The MDASM has one dedicated external signal. This signal is used in input or in output depending on the selected mode. When in input, it allows the MDASM to perform input capture, input pulse width measurement and input period measurement. When in output, it allows output compare, single shot output pulse, single output compare and output port bit operations as well as output pulse width modulation.

#### NOTE

In disable mode, the signal becomes a high impedance input and the input level on this signal is reflected by the state of the PIN bit in the MDASMSR register.

### 17.9.2 MDASM Description

The MDASM contains two timing channels A and B associated with the same input/output signal. The dual action submodule is so called because its timing channel configuration allows two events (input capture or output compare) to occur before software intervention is required.

Six operating modes allow the software to use the MDASM's input capture and output compare functions to perform pulse width measurement, period measurement, single pulse generation and continuous pulse width generation, as well as standard input capture and output compare. The MDASM can also work as a single I/O signal. See [Table 17-16](#) for details.

Channel A comprises one 16-bit data register and one 16-bit comparator. Channel B also consists of one 16-bit data register and one 16-bit comparator, however, internally, channel B has two data registers B1 and B2, and the operating mode determines which register is accessed by the software:

- In the input modes (IPWM, IPM and IC), registers A and B2 are used to hold the captured values; in these modes, the B1 register is used as a temporary latch for channel B.
- In the output compare modes (OCB and OCAB), registers A and B2 are used to define the output pulse; register B1 is not used in these modes.
- In the output pulse width modulation mode (OPWM), registers A and B1 are used as primary registers and hidden register B2 is used as a double buffer for channel B.

Register contents are always transferred automatically at the correct time so that the minimum pulse (measurement or generation) is just one 16-bit counter bus count. The A and B data registers are always read/write registers, accessible via the MIOB.

In the input modes, the edge detect circuitry triggers a capture whenever a rising or falling edge (as defined by the EDPOL bit) is applied to the input signal. The signal on the input signal is Schmitt triggered and synchronized with the MIOS14 CLOCK.

In the disable mode (DIS) and in the input modes, the PIN bit reflects the state present on the input signal (after being Schmitt triggered and synchronized). In the output modes the PIN bit reflects the value present on the output flip-flop. The output flip-flop is used in output modes to hold the logic level applied to the output signal.

The 16-bit counter bus selector is common to all input and output functions; it connects the MDASM to one of the four 16-bit counter buses available to that submodule instance and is controlled in software by the 16-bit counter bus selector bits BSL0 and BSL1 in the MDASMSCR register.

### 17.9.3 MDASM Modes of Operation

The mode of operation of the MDASM is determined by the mode select bits MODE[0:3] in the MDASMSCR register (see [Table 17-16](#)).

**Table 17-16. MDASM Modes of Operation**

| MODE[0:3] | Mode | Description of Mode                                                                                                    |
|-----------|------|------------------------------------------------------------------------------------------------------------------------|
| 0000      | DIS  | Disabled — Input signal is high impedance; PIN gives state of the input signal.                                        |
| 0001      | IPWM | Input pulse width measurement — Capture on the leading edge and the trailing edge of an input pulse.                   |
| 0010      | IPM  | Input period measurement — Capture two consecutive rising/falling edges.                                               |
| 0011      | IC   | Input capture — Capture when the designated edge is detected.                                                          |
| 0100      | OCB  | Output compare, flag line activated on B compare — Generate leading and trailing edges of an output pulse.             |
| 0101      | OCAB | Output compare, flag line activated on A and B compare — Generate leading and trailing edges of an output pulse.       |
| 1xxx      | OPWM | Output pulse width modulation — Generate continuous PWM output with 7, 9, 11, 12, 13, 14, 15 or 16 bits of resolution. |

To avoid spurious interrupts, and to make sure that the FLAG line is activated according to the newly selected mode, the following sequence of operations should be adopted when changing mode:

1. Disable MDASM interrupts (by resetting the enable bit in the relevant MIRSM)
2. Change mode (via disable mode)
3. Reset the corresponding FLAG bit in the relevant MIRSM
4. Re-enable MDASM interrupts (if desired)

#### NOTE

When changing between output modes, it is not necessary to follow this procedure, as in these modes the FLAG bit merely indicates to the software that the compare value can be updated. However changing modes without passing via the disable mode does not guarantee the subsequent functionality.

#### 17.9.3.1 Disable (DIS) Mode

The disable mode is selected by setting MODE[0:3] to 0b0000.

In this mode, all input capture and output compare functions of the MDASM are disabled and the FLAG line is maintained inactive, but the input port signal function remains available. The associated signal becomes a high impedance input and the input level on this signal is reflected by the state of the PIN bit in the MDASMSCR register. All control bits remain accessible, allowing the software to prepare for future

mode selection. Data registers A and B are accessible at consecutive addresses. Writing to data register B stores the same value in registers B1 and B2.

### WARNING

When changing modes, it is imperative to go through the DIS mode. Failure to do this could lead to invalid and unexpected output compare or input capture results, and to flags being set incorrectly.

### 17.9.3.2 Input Pulse Width Measurement (IPWM) Mode

IPWM mode is selected by setting MODE[0:3] to 0b0001.

This mode allows the width of a positive or negative pulse to be determined by capturing the leading edge of the pulse on channel B and the trailing edge of the pulse on channel A; successive captures are done on consecutive edges of opposite polarity. The edge sensitivity is selected by the EDPOL bit in the MDASMSCR register.

This mode also allows the software to determine the logic level on the input signal at any time by reading the PIN bit in the MDASMSCR register.

The channel A input capture function remains disabled until the first leading edge triggers the first input capture on channel B (refer to [Figure 17-16](#)). When this leading edge is detected, the count value of the 16-bit counter bus selected by the BSL[1:0] bits is latched in the 16-bit data register B1; the FLAG line is not activated. When the next trailing edge is detected, the count value of the 16-bit counter bus is latched into the 16-bit data register A and, at the same time, the FLAG line is activated and the contents of register B1 are transferred to register B2.

Reading data register B returns the value in register B2. If subsequent input capture events occur while the FLAG bit is set in the corresponding MIRSM, data registers A and B will be updated with the latest captured values and the FLAG line will remain active.

If a 32-bit coherent operation is in progress when the trailing edge is detected, the transfer from B1 to B2 is deferred until the coherent operation is completed. Operation of the MDASM then continues on channels B and A as previously described.

The input pulse width is calculated by subtracting the value in data register B from the value in data register A.

[Figure 17-16](#) provides an example of how the MDASM can be used for input pulse width measurement.

Mode selection; EDPOL = 1 (Channel A capture on falling edge, Channel B capture on rising edge)

Figure 17-16. Input Pulse Width Measurement Example

### 17.9.3.3 Input Period Measurement (IPM) Mode

IPM mode is selected by setting MODE[0:3] to 0b0010.

This mode allows the period of an input signal to be determined by capturing two consecutive rising edges or two consecutive falling edges; successive input captures are done on consecutive edges of the same polarity. The edge sensitivity is defined by the EDPOL bit in the MDASMSCR register.

This mode also allows the software to determine the logic level on the input signal at any time by reading the PIN bit in the MDASMSCR register (refer to Figure 17-17). When the first edge having the selected polarity is detected, the 16-bit counter bus value is latched into the 16-bit data register A. Data in register B1 is transferred to data register B2 and the data in register A is transferred to register B1.

On this first capture the FLAG line is not activated, and the value in register B2 is meaningless. On the second and subsequent captures, the FLAG line is activated when the data in register A is transferred to register B1.

When the second edge of the same polarity is detected, the counter bus value is latched into data register A, the data in register B1 is transferred to data register B2, the FLAG line is activated to signify that the beginning and end points of a complete period have been captured, and finally the data in register A is transferred to register B1. This sequence of events is repeated for each subsequent capture. Reading data register B returns the value in register B2.

If a 32-bit coherent operation is in progress when an edge (except for the first edge) is detected, the transfer of data from B1 to B2 is deferred until the coherent operation is completed. At any time, the input level present on the input signal can be read on the PIN bit.

The input pulse period is calculated by subtracting the value in data register B from the value in data register A.

Figure 17-17 provides an example of how the MDASM can be used for input period measurement.

Figure 17-17. Input Period Measurement Example

### 17.9.3.4 Input Capture (IC) Mode

IC mode is selected by setting MODE[0:3] to 0b0011.

This mode is identical to the input period measurement mode (IPM) described above, with the exception that the FLAG line is also activated at the occurrence of the first detected edge of the selected polarity. In this mode the MDASM functions as a standard input capture function. In this case the value latched in channel B can be ignored. Figure 17-18 provides an example of how the MDASM can be used for input capture.

Figure 17-18. MDASM Input Capture Example

### 17.9.3.5 Output Compare (OCB and OCAB) Modes

Output compare mode (either OCA or OCB) is selected by setting MODE[0:3] to 0b010x. The MODE0 controls the activation criteria for the FLAG line, (i.e., when a compare occurs only on channel B or when a compare occurs on either channel).

This mode allows the MDASM to perform four different output functions:

- Single-shot output pulse (two edges), with FLAG line activated on the second edge
- Single-shot output pulse (two edges), with FLAG line activated on both edges
- Single-shot output transition (one edge)
- Output port signal, with output compare function disabled

In this mode the leading and trailing edges of variable width output pulses are generated by calculated output compare events occurring on channels A and B, respectively. OC mode may also be used to perform a single output compare function, or may be used as an output port bit.

In this mode, channel B is accessed via register B2. A write to register B2 writes the same value to register B1 even though the contents of B1 are not used in this mode. Both channels work together to generate one ‘single shot’ output pulse signal. Channel A defines the leading edge of the output pulse, while channel B defines the trailing edge of the pulse. FLAG line activation can be done when a match occurs on channel B only or when a compare occurs on either channel (as defined by the MODE0 in the MDASMSR register).

When this mode is first selected, (i.e., coming from disable mode, both comparators are disabled). Each comparator is enabled by writing to its data register; it remains enabled until the next successful comparison is made on that channel, whereupon it is disabled. The values stored in registers A and B are compared with the count value on the selected 16-bit counter bus when their corresponding comparators are enabled.

The output flip-flop is set when a match occurs on channel A. The output flip-flop is reset when a match occurs on channel B. The polarity of the output signal is selected by the EDPOL bit. The output flip-flop level can be obtained at any time by reading the PIN bit.

If subsequent enabled output compares occur on channels A and B, the output pulses continue to be output, regardless of the state of the FLAG bit.

At any time, the FORCA and FORCB bits allow the software to force the output flip-flop to the level corresponding to a comparison on channel A or B, respectively.

#### NOTE

The FLAG line is not affected by these ‘force’ operations.

Totem pole or open-drain output circuit configurations can be selected using the WOR bit in the MDASMSR register.

#### NOTE

If both channels are loaded with the same value, the output flip-flop provides a logic zero level output and the flag bit is still set on the match.

#### NOTE

16-bit counter bus compare only occurs when the 16-bit counter bus is updated.

### 17.9.3.5.1 Single Shot Output Pulse Operation

The single shot output pulse operation is selected by writing the leading edge value of the desired pulse to data register A and the trailing edge value to data register B. A single pulse will be output at the desired time, thereby disabling the comparators until new values are written to the data registers. To generate a single shot output pulse, the OCB mode should be used to only generate a flag on the B match.

In this mode, registers A and B2 are accessible to the user software (at consecutive addresses).

[Figure 17-19](#) provides an example of how the MDASM can be used to generate a single output pulse.

Figure 17-19. Single Shot Output Pulse Example

### 17.9.3.5.2 Single Output Compare Operation

The single output compare operation is selected by writing to only one of the two data registers (A or B), thus enabling only one of the comparators. Following the first successful match on the enabled channel, the output level is fixed and remains at the same level indefinitely with no further software intervention being required. To generate a single output compare, the OCAB mode should be used to generate a flag on both the A and the B match.

#### NOTE

In this mode, registers A and B2 are accessible to the user software (at consecutive addresses).

Figure 17-20 provides an example of how the MDASM can be used to perform a single output compare.

Figure 17-20. Single Shot Output Transition Example

### 17.9.3.5.3 Output Port Bit Operation

The output port bit operation is selected by leaving both channels disabled, (i.e., by writing to neither register A nor B). The EDPOL bit alone controls the output value. The same result can be achieved by keeping EDPOL at zero and using the FORCA and FORCB bits to obtain the desired output level.

### 17.9.3.6 Output Pulse Width Modulation (OPWM) Mode

OPWM mode is selected by setting MODE[0:3] to 1xxx. The MODE[1:3] bits allow some of the comparator bits to be masked.

This mode allows pulse width modulated output waveforms to be generated, with eight selectable frequencies. Frequencies are only relevant as such if the counter bus is driven by a counter as a time reference. Both channels (A and B) are used to generate one PWM output signal on the MDASM signal.

Channel B is accessed via register B1. Register B2 is not accessible. Channels A and B define respectively the leading and trailing edges of the PWM output pulse. The value in register B1 is transferred to register B2 each time a match occurs on either channel A or B.

#### NOTE

A FORCA or FORCB does not cause a transfer from B1 to B2.

The value loaded in register A is compared with the value on the 16-bit counter bus each time the counter bus is updated. When a match on A occurs, the FLAG line is activated and the output flip-flop is set. The value loaded in register B2 is compared with the value on the 16-bit counter bus each time the counter bus is updated. When a match occurs on B, the output flip-flop is reset.

### NOTE

If both channels are loaded with the same value, when a simultaneous match on A and B occurs, the submodule behaves as if a simple match on B had occurred except for the FLAG line which is activated. The output flip-flop is reset and the value in register B1 is transferred to register B2 on the match.

The polarity of the PWM output signal is selected by the EDPOL bit. The output flip-flop level can be obtained at any time by reading the PIN bit.

If subsequent compares occur on channels A and B, the PWM pulses continue to be output, regardless of the state of the FLAG bit.

At any time, the FORCA and FORCB bits allow the software to force the output flip-flop to the level corresponding to a comparison on A or B respectively. Note that the FLAG line is not activated by the FORCA and FORCB operations.

### WARNING

Data registers A and B must be loaded with the values needed to produce the desired PWM output pulse.

### NOTE

16-bit counter bus compare only occurs when the 16-bit counter bus is updated.

Figure 17-21 provides an example of how the MDASM can be used for pulse width modulation.

**Figure 17-21. MDASM Output Pulse Width Modulation Example**

To generate PWM output pulses of different frequencies, the 16-bit comparator can have some of its bits masked. This is controlled by bits MODE2, MODE1 and MODE0. The frequency of the PWM output ( $f_{PWM}$ ) is given by the following equation (assuming the MDASM is connected to a 16-bit counter bus used as time reference and  $f_{SYS}$  is the frequency of the MIOS14 CLOCK):

$$f_{\text{PWM}} = \frac{f_{\text{SYS}}}{N_{\text{MCPSM}} \cdot N_{\text{COUNTER}} \cdot N_{\text{MDASM}}}$$

where:

- $N_{\text{MCPSM}}$  is the overall MCPSM clock divide ratio (2, 3, 4,...,16).
- $N_{\text{COUNTER}}$  is the divide ratio of the prescaler of the counter (used as a time reference) that drives the 16-bit counter bus.
- $N_{\text{MDASM}}$  is the maximum count reachable by the counter when using  $n$  bits of resolution (this count is equal to  $2^n$ ).

A few examples of frequencies and resolutions that can be obtained are shown in [Table 17-17](#).

**Table 17-17. MDASM PWM Example Output Frequencies/Resolutions at  $f_{\text{SYS}} = 40 \text{ MHz}$**

| Resolution (bits) | $N_{\text{MCPSM}}$ | $N_{\text{COUNTER}}$ | $N_{\text{MDASM}}$ | PWM output frequency (Hz) <sup>1</sup> |
|-------------------|--------------------|----------------------|--------------------|----------------------------------------|
| 16                | 16                 | 256                  | 65536              | 0.15                                   |
| 16                | 2                  | 1                    | 65536              | 305.17                                 |
| 15                | 16                 | 256                  | 32768              | 0.29                                   |
| 15                | 2                  | 1                    | 32768              | 610.35                                 |
| 14                | 16                 | 256                  | 16384              | 0.59                                   |
| 14                | 2                  | 1                    | 16384              | 1 220.70                               |
| 13                | 16                 | 256                  | 8192               | 1.19                                   |
| 13                | 2                  | 1                    | 8192               | 2 441.41                               |
| 12                | 16                 | 256                  | 4096               | 2.38                                   |
| 12                | 2                  | 1                    | 4096               | 4 882.81                               |
| 11                | 16                 | 256                  | 2048               | 4.77                                   |

<sup>1</sup> This information is valid only if the MDASM is connected to an MMCSM operating as a free-running counter.

When using 16 bits of resolution on the comparator ( $\text{MODE}[2:0] = 0b000$ ), the output can vary from a 0% duty cycle up to a duty cycle of 65535/65536. In this case it is not possible to have a 100% duty cycle. In cases where 16-bit resolution is not needed, it is possible to have a duty cycle ranging from 0% to 100%. Setting bit 15 of the value stored in register B to one results in the output being ‘always set’. Clearing bit 15 (to zero) allows normal comparisons to occur and the normal output waveform is obtained. Changes to and from the 100% duty cycle are done synchronously on an A or B match, as are all other width changes.

In the OPWM mode, the WOR bit selects whether the output is totem pole driven or open-drain.

### 17.9.4 Modular I/O Bus (MIOB) Interface

- The MDASM is connected to all the signals in the read/write and control bus, to allow data transfer from and to the MDASM registers, and to control the MDASM in the different possible situations.
- The MDASM is connected to four 16-bit counter buses available to that submodule instance, so that the MDASM can select by software which one to use.
- The MDASM uses the request bus to transmit the FLAG line to the interrupt request submodule (MIRSM).

### 17.9.5 Effect of RESET on MDASM

When the reset signal is asserted, the MDASM registers are reset according to the values specified in [Section 17.9.6, “MDASM Registers.”](#)

### 17.9.6 MDASM Registers

The privilege level to access the MDASM registers depends on the MIOS14MCR[SUPV]. The privilege level is unrestricted after reset and can be changed to supervisor by software.

#### 17.9.6.1 MDASM Registers Organization

The MDASM register map comprises four 16-bit register locations. As shown in below, the register block contains four MDASM registers. Note that the MDASMSCRD is the duplication of the MDASMSCR. This is done to allow 32-bit aligned accesses.

#### WARNING

The user should not write directly to the address of the MDASMSCRD. This register’s address may be reserved for future use and should not be accessed by the software to ensure future software compatibility.

All unused bits return zero when read by the software. All register addresses in this section are specified as offsets from the base address of the MDASM.

**Table 17-18. MDASM Address Map**

| Address        | Register                                                                                                                           |

**Table 17-20. MDASMBR Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
|------|------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:15 | BR   | <p>MDASMBR is the data register associated with channel B; its use varies with the different modes of operation.</p> <p>Writing to register B always writes to B1 and, depending on the mode selected, sometimes to B2. Reading register B either reads B1 or B2 depending on the mode selected.</p> <p>In the DIS mode, MDASMBR can be accessed to prepare a value for a subsequent mode selection. In this mode, register B1 is accessed in order to prepare a value for the OPWM mode. Unused register B2 is hidden and cannot be read, but is written with the same value when register B1 is written.</p> <p>In the IPWM mode, MDASMBR contains the captured value corresponding to the leading edge of the measured pulse. In this mode, register B2 is accessed; buffer register B1 is hidden and is not readable.</p> <p>In the IPM and IC modes, MDASMBR contains the captured value corresponding to the previously dedicated edge (rising or falling edge). In this mode, register B2 is accessed; buffer register B1 is hidden and is not readable.</p> <p>In the OCB and OCAB modes, MDASMBR is loaded with the value corresponding to the trailing edge of the pulse to be generated. Writing to MDASMBR in the OCB and OCAB modes also enables the corresponding channel B comparator until the next successful comparison. In this mode, register B2 is accessed; buffer register B1 is hidden and is not readable.</p> <p>In the OPWM mode, MDASMBR is loaded with the value corresponding to the trailing edge of the PWM pulse to be generated. In this mode, register B1 is accessed; buffer register B2 is hidden and cannot be accessed.</p> <p>NOTE: In IC, IPM, or IPWM mode, when a read to register A or B occurs at the same time as a counter bus capture into that register and the counter bus is changing value, then the counter bus capture to that register is delayed.</p> |

#### 17.9.6.4 MDASM Status/Control Register (MDASMSCRD) (Duplicated)

The MDASMSCRD and the MDASMSCR are the same registers accessed at two different addresses.

Reading or writing to one of these two addresses has exactly the same effect.

#### WARNING

The user should not write directly to the address of the MDASMSCRD. This register's address may be reserved for future use and should not be accessed by the software to ensure future software compatibility.

The duplication of the SCR register allows coherent 32-bit accesses when using an RCPU.

#### 17.9.6.5 MDASM Status/Control Register (MDASMSCR)

The status and control register gathers a read only bit reflecting the status of the MDASM signal as well as read/write bits related to its control and configuration.

The signal input status bit reflects the status of the corresponding signal when in input mode. When in output mode, the PIN bit only reflects the status of the output flip-flop.

| Bits | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|------|-------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | PIN   | Pin Input Status — The pin input status bit reflects the status of the corresponding bit.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 1    | WOR   | Wired-OR bit — In the DIS, IPWM, IPM and IC modes, the WOR bit is not used; reading this bit returns the value that was previously written.<br>In the OCB, OCAB and OPWM modes, the WOR bit selects whether the output buffer is configured for open-drain or totem pole operation. When open-drain mode is selected, the EDPOL bit is not used; writing to EDPOL will have no effect on the output voltage.<br>1 Output buffer is open-drain.<br>0 Output buffer is totem pole.<br>The WOR bit is cleared by reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 2    | FREN  | Freeze enable bit — This active high read/write control bit enables the MDASM to recognize the MIOB freeze signal.<br>1 = The MDASM is frozen if the MIOB freeze line is active.<br>0 = The MDASM is not frozen even if the MIOB freeze line is active.<br>The FREN is cleared by reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 3    | —     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 4    | EDPOL | Polarity bit — In the DIS mode, this bit is not used; reading it returns the last value written.<br>In the IPWM mode, this bit is used to select the capture edge sensitivity of channels A and B.<br>1 Channel A captures on a falling edge. Channel B captures on a rising edge.<br>0 Channel A captures on a rising edge. Channel B captures on a falling edge.<br>In the IPM and IC modes, the EDPOL bit is used to select the input capture edge sensitivity of channel A.<br>1 Channel A captures on a falling edge.<br>0 Channel A captures on a rising edge.<br>In the OCB, OCAB and OPWM modes, the EDPOL bit is used to select the voltage level on the output signal. If open-drain mode is selected via the WOR bit, the EDPOL bit is disabled and writing to it will have no effect on the output voltage.<br>1 The complement of the output flip-flop logic level appears on the output signal: a match on channel A resets the output signal; a match on channel B sets the output signal.<br>0 The output flip-flop logic level appears on the output signal: a match on channel A sets the output signal, a match on channel B resets the output signal.<br>The EDPOL bit is cleared by reset. |
| 5    | FORCA | Force A bit — In the OCB, OCAB and OPWM modes, the FORCA bit allows the software to force the output flip-flop to behave as if a successful comparison had occurred on channel A (except that the FLAG line is not activated). Writing a one to FORCA sets the output flip-flop; writing a zero to it has no effect.<br>In the DIS, IPWM, IPM and IC modes, the FORCA bit is not used and writing to it has no effect. FORCA is cleared by reset and is always read as zero.<br>Writing a one to both FORCA and FORCB simultaneously resets the output flip-flop.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

**Table 17-21. MDASMSCR Bit Descriptions (continued)**

| Bits  | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|-------|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 6     | FORCB | Force B bit — In the OCB, OCAB and OPWM modes, the FORCB bit allows the software to force the output flip-flop to behave as if a successful comparison had occurred on channel B (except that the FLAG line is not activated). Writing a one to FORCB resets the output flip-flop; writing a zero to it has no effect.<br>In the DIS, IPWM, IPM and IC modes, the FORCB bit is not used and writing to it has no effect. FORCB is cleared by reset and is always read as zero.<br>Writing a one to both FORCA and FORCB simultaneously resets the output flip-flop. |
| 7:8   | —     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 9:10  | BSL   | Bus select bits — These bits are used to select which of the six 16-bit counter buses is used by the MDASM. Each MDASM instance has four possible counter buses that may be connected. See <a href="#">Table 17-23</a> for more information.<br><b>NOTE:</b> Unconnected counter buses inputs are grounded.                                                                                                                                                                                                                                                         |
| 11    | —     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 12:15 | MODE  | Mode select bits — The four mode select bits select the mode of operation of the MDASM. To avoid spurious interrupts, it is recommended that MDASM interrupts are disabled before changing the operating mode.<br>The mode select bits are cleared by reset.<br><b>NOTE:</b> The reserved modes should not be set; if these modes are set, the MDASM behavior is undefined.                                                                                                                                                                                         |

**Table 17-22. MDASM Mode Selects**

| MDASM Control Register Bits | Bits of Resolution | Counter Bus Bits Ignored | MDASM Mode of Operation                        |
|-----------------------------|--------------------|--------------------------|------------------------------------------------|
| MODE                        |                    |                          |                                                |

## 17.10 MIOS14 Pulse Width Modulation Submodule (MPWMSM)

The MIOS14 pulse width modulation submodule (MPWMSM) is a function included in the MIOS14 library. It allows pulse width modulated signals to be generated over a wide range of frequencies, independently of other MIOS14 output signals and with no software intervention. The output pulse width can vary from 0% to 100%. The minimum pulse width is twice the minimum MIOS14 CLOCK period (i.e., the minimum pulse width is 50 ns when  $f_{SYS}$  is 40 MHz). The MPWMSM can run in a double-buffered mode, to avoid spurious update.

The following sections describe the MPWMSM in detail. A block diagram of the MPWMSM is shown in [Figure 17-25](#).

Figure 17-25. MPWMSM Block Diagram

### 17.10.1 MPWMSM Terminology

Terminology used in the MIOS14 pulse width modulation submodule includes the following:

|                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|--------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Bits of resolution | The MPWMSM contains a 16-bit modulus down-counter that counts from the desired loaded value to 0x0001. The term “bits of resolution” is used in this document to indicate the size of the equivalent free running binary counter. To cover the worst case, the number of bits is rounded to the lower number. For example, if the counter is preset with a value between 128 and 255, it is said to have seven bits of resolution. If it is preset with a value between 256 and 511, it is said to have eight bits of resolution, and so on. |
| Resolution         | The term “resolution” is used in this document to define the minimum MPWMSM output increment in time units.                                                                                                                                                                                                                                                                                                                                                                                                                                  |

### 17.10.2 MPWMSM Features

- Output pulse width modulated (PWM) signal generation with no software intervention
- Built-in 8-bit programmable prescaler clocked by the MCPSM

- PWM period and pulse width values provided by software:
  - Double-buffered for glitch-free period and pulse width changes
  - Minimum output period/pulse-width increment: 50 ns (assuming  $f_{SYS} = 40$  MHz)
  - Maximum 50% duty-cycle output frequency: 10 MHz (assuming  $f_{SYS} = 40$  MHz)
  - Up to 16 bits of resolution for the output pulse width
  - Wide range of periods
    - 16 bits of resolution: period range from 3.27 ms (with 50-ns steps) to 6.71 s (with 102.4  $\mu$ s steps)
    - Eight bits of resolution: period range from 12.8  $\mu$ s (with 50-ns steps) to 26.2 ms (with 102.4- $\mu$ s steps)
  - Wide range of frequencies
    - Maximum output frequency at  $f_{SYS} = 40$  MHz with 16 bits of resolution and divide-by-2 prescaler selection: 305 Hz (3.27 ms.)
    - Minimum output frequency at  $f_{SYS} = 40$  MHz with 16 bits of resolution and divide-by-4096 prescaler selection: 0.15 Hz (6.7 s.)
    - Maximum output frequency at  $f_{SYS} = 40$  MHz with 8 bits of resolution and divide-by-2 prescaler selection: 78125 Hz (12.8  $\mu$ s.)
    - Minimum output frequency at  $f_{SYS} = 40$  MHz with 8 bits of resolution and divide-by-4096 prescaler selection: 38.15 Hz (26.2 ms.)
- Programmable duty cycle from 0% to 100%
- Possible interrupt generation at start of every period
- Software selectable output pulse polarity
- Software readable output signal status
- Possible use of signal as I/O port when PWM function is not needed

### 17.10.3 MPWMSM Description

The purpose of the MPWMSM is to create a variable pulse width output signal at a wide range of frequencies, independently of other MIOS14 output signals. The MPWMSM includes its own counter, and thus does not use the MIOS14 counter bus set. However the MPWMSM uses the prescaled clock bus that originates in the MIOS14 counter prescaler submodule (MCPSM). The MPWMSM pulse width can vary from 0% to 100%, with up to 16 bits of resolution. The finest output resolution is the MIOS14 CLOCK period multiplied by two (for a MIOS14 CLOCK with  $f_{SYS} = 40$  MHz, the finest output pulse width resolution is 50 ns). With the full 16 bits of resolution and the MCPSM set to divide by two, the period of the output signal can range from 3.276 ms to 6.71 s (assuming  $f_{SYS} = 40$  MHz).

By reducing the amount of bits of resolution, the output signal period can be reduced. For example, the period can be as fast as 204.8  $\mu$ s (4882 Hz) with 12 bits of resolution, as fast as 12.8  $\mu$ s (78.125 KHz) with eight bits of resolution, and as fast as 3.2  $\mu$ s (312.5 KHz) with six bits of resolution (still assuming a  $f_{SYS} = 40$  MHz and the MCPSM set to divide by two).

The MPWMSM is composed of:

- An output flip-flop with output buffer and polarity control
- An input/output signal with data direction control
- An 8-bit prescaler and clock selection logic
- A 16-bit down-counter (MPWMCNTR)
- A register to hold the next period values (MPWMPERR)
- Two registers to hold the current and next pulse width values (MPWMPULR)
- A less-than or equal comparator
- A status and control register (MPWMSCR)

### 17.10.3.1 Clock Selection

The MPWMSM contains an 8-bit prescaler clocked by the output signal from the MIOS14 counter prescaler submodule ( $f_{SYS}/2$  to  $f_{SYS}/16$ ). The MPWMSM clock selector allows the choice, by software, of one of 256 divide ratios which give to the MPWMSM a large choice of frequencies available for the down-counter. The MPWMSM down-counter is thus capable of counting with a clock frequency ranging from  $f_{SYS}/2$  to  $f_{SYS}/4096$ .

Switching the MPWMSM from disable to enable will reload the value of MPWMSCR[CP] into the 8-bit prescaler counter.

### 17.10.3.2 Counter

A 16-bit down-counter in the MPWMSM provides the time reference for the output signal. The counter is software writable. When writing to the counter (i.e., at the MPWMCNTR address), it also writes to the MPWMPERR register. When in transparent mode ( $TRSP = 1$ ), writing to the MPWMPERR will also write to the counter. The down-counter is readable at anytime. The value loaded in the down-counter corresponds to the period of the output signal.

When the MPWMSM is enabled, the counter begins counting. As long as it is enabled, the counter counts down freely. The counter counts at the rate established by the prescaler. When the count down reaches 0x0001, the load operation is executed and the value in the MPWMPERR register is loaded in the MPWMCNTR register, (i.e., the counter). Then the counter restarts to count down from that value.

### 17.10.3.3 Period Register

The period section is composed of a 16-bit data register (MPWMPERR). The software establishes the period of the output signal in register MPWMPERR.

When the MPWMSM is running in transparent mode, the period value in register MPWMPERR is immediately transferred to the counter on a write to the MPWMPERR.

When the MPWMSM is running in double-buffered mode, the period value in register MPWMPERR can be changed at any time without affecting the current period of the output signal. The new value of MPWMPERR will be transferred to the counter only when the counter reaches the value of 0x0001 and generates a load signal.

Period values of 0x0000, 0x0001, and 0x0002 are MPWMSM special cases:

- The value 0x0000 in the period register, causes the counter to act like a free running counter. This condition creates a period of 65536 PWM clock periods.
- The value 0x0001 in the period register will always cause a period match to occur and the counter will never decrement below 0x0001. This condition is defined as a period of “1” PWM clock count. The output flip-flop is always set unless MPWMPULR = 0x0000, when the output flip-flop is always reset. Refer to [Section 17.10.3.5, “Duty Cycles \(0% and 100%\)”](#) for details about 0% and 100% duty cycles.
- Writing value 0x0002 in the period register causes a period match to occur every two clock periods. The counter decrements from 0x0002 to 0x0001, and then it is initialized back to 0x0002. This condition is defined as a period of 2 clock counts. Note that the value 0x0002 loaded in the period register and a value of 0x0001 in the pulse width register is the condition to obtain the maximum possible output frequency for a given clock period.

The relationship between the output frequency obtained ( $F_{P_{WMO}}$ ) and the MIOS14 CLOCK frequency ( $f_{SYS}$ ), the MCPSM clock divide ratio ( $N_{MCPSM}$ ), the counter divide ratio ( $N_{MPWMSM}$ ) and the value loaded in the counter ( $V_{COUNTER}$ ) is given by the following equation:

$$f_{P_{WMO}} = \frac{f_{SYS}}{N_{MCPSM} \cdot N_{MPWMSM} \cdot V_{COUNTER}}$$

#### 17.10.3.4 Pulse Width Registers

The pulse width section is composed of two 16-bit data registers (MPWMPULR1 and MPWMPULR2). Only MPWMPULR1 is accessible by software. The software establishes the pulse width of the MPWMSM output signal in MPWMPULR1. MPWMPULR2 is used as a double buffer of MPWMPULR1.

When the MPWMSM is running in transparent mode, the pulse width value in MPWMPULR1 is immediately transferred in MPWMPULR2 so that the new value takes effect immediately.

#### NOTE

When the MPWMSM is in disable mode, writing to MPWMPULR1 will write automatically to MPWMPULR2.

When the MPWMSM is not running in double-buffered mode, the pulse width value in MPWMPULR1 can be changed at any time without affecting the current pulse width of the output signal. The new value in MPWMPULR1 will be transferred to MPWMPULR2 only when the down-counter reaches the value of 0x0001.

When the counter first reaches the value in MPWMPULR2, the output flip-flop is set. The output is reset when the counter reaches 0x0001. The pulse width match starts the width of the output signal, it does not affect the counter. MPWMPULR1 is software readable and writable at any time. The MPWMSM does not modify the content of MPWMPULR1.

The PWM output pulse width can be as wide as one period minus one MPWMSM clock count: (i.e.,  $MPWMPULR2 = MPWMPERR - [one\ MPWMSM\ clock\ count]$ ). At the other end of the pulse width range, MPWMPULR2 can contain 0x0001 to create a pulse width of one PWM clock count.

For example, with 0x00FF in the counter and 0x0002 in MPWMPULR2, the period is 255 PWM clock count and the pulse width is 2 PWM clock counts.

For a given system clock frequency, with a given counter divide ratio and clock selection divide ratio, the output pulse width is given by the following equation:

$$\text{Pulse_Width} = \frac{N_{\text{MCPSM}}^2 N_{\text{MPWMSM}}^2 V_{\text{MPWMB2}}}{f_{\text{SYS}}}$$

where  $V_{\text{MPWMB2}}$  is the value in the register B2

In such conditions, the minimum output pulse width that can be obtained is given by:

$$\text{Minimum_Pulse_Width} = \frac{N_{\text{MCPSM}}^2 N_{\text{MPWMSM}}}{f_{\text{SYS}}}$$

and the maximum pulse width by:

$$\text{Maximum_Pulse_Width} = \frac{N_{\text{MCPSM}}^2 N_{\text{MPWMSM}}^2 (2^{\text{Bit\_of\_Resolution}} - 1)}{f_{\text{SYS}}}$$

### 17.10.3.5 Duty Cycles (0% and 100%)

The 0% and 100% duty cycles are special cases to give flexibility to the software to create a full range of outputs. The “always set” and “always clear” conditions of the output flip-flop are established by the value in register MPWMPULR2. These boundary conditions are generated by software, just like another pulse. When the PWM output is being used to generate an analog level, the 0% and 100% represent the full scale values.

The 0% output is created with a 0x0000 in register MPWMPULR2, which prevents the output flip-flop from ever being set.

The 100% output is created when the content of register MPWMPULR2 is equal to or greater than the content of register MPWMPERR. Thus, the width register match occurs on counter reload. The state sequencer provides the timing to ensure that the first appearance of a 100% value in register MPWMPULR2 causes a glitchless always-set condition of the output flip-flop when TRSP = ‘0’.

#### NOTE

Even if the output is forced to 100%, the 16-bit up counter continues its counting and that output changes to or from the 100% value are done synchronously to the selected period.

#### NOTE

When a PWM output period is selected to be 65536 PWM clocks by loading 0x0000 in the period register, it is not possible to have an 100% duty cycle output signal. In this case, the maximum duty cycle available is of 65535/65536.

### 17.10.3.6 Pulse/Frequency Range Table

Table 17-24 summarizes the frequency and minimum pulse width values that can be obtained respectively with divide-by-1 and divide-by-256 MPWMSM clock prescaler options, while using a MIOS14 CLOCK frequency of 40 MHz, and for each MCPSM clock divide ratios.

**Table 17-24. PWM Pulse/Frequency Ranges (in Hz) Using /1 or /256 Option (40 MHz)**

| Minimum Pulse Width | Bits of Resolution |       |       |       |       |       |        |        |        |        |        |        |        |        |        |         |
|---------------------|--------------------|-------|-------|-------|-------|-------|--------|--------|--------|--------|--------|--------|--------|--------|--------|---------|
|                     | 16                 | 15    | 14    | 13    | 12    | 11    | 10     | 9      | 8      | 7      | 6      | 5      | 4      | 3      | 2      | 1       |
| With /1 Option      |                    |       |       |       |       |       |        |        |        |        |        |        |        |        |        |         |

### 17.10.3.7 MPWMSM Status and Control Register (SCR)

One register is used to initialize the MPWMSM and monitor its operation. Control bits are included to allow the software to enable the PWM generator, establish the output signal polarity, select the counter clock rate and set the glitch-free mode. A status bit is included to allow the software to read the state of the output signal.

### 17.10.3.8 MPWMSM Interrupt

A valid MPWMSM interrupt is recognized when a pulse occurs on the flag line to set the flag bit and the interrupt enable bit is set for the corresponding level in the MIRSM (Refer to [Section 17.12, “MIOS14 Interrupts,”](#) [Section 17.12.1, “MIOS14 Interrupt Structure”](#) and [Section 17.12.2, “MIOS14 Interrupt Request Submodule \(MIRSM\)”](#) for details about interrupts). A set flag pulse is generated at the start of every period.

The flag bit is a status bit which indicates, when set, that the output period has started and that registers MPWMPERR and MPWMPULR1 are available for updates when in double-buffered mode. The level of the resulting interrupt is determined in the MIRSM.

### 17.10.3.9 MPWMSM Port Functions

The MPWMSM has one dedicated I/O external signal.

The output flip-flop is the basic output of the MPWMSM. Except when the pulse width is at 100% or 0%, the output flip-flop is reset at the beginning of each period and is set at the beginning of the designated pulse width until the end of the period. As a software option, the polarity of the signal presented to the output signal may be the state of the output flip-flop or the inverse of the output flip-flop.

The MPWMSM is connected to an external, input/output signal. When in the disabled mode, the POL bit (polarity) and the DDR bit (data direction) in the SCR register allow the MPWMSM to be used as an I/O port.

### 17.10.3.10 MPWMSM Data Coherency

Byte accesses to MPWMPULR and MPWMPERR are supported, but are not recommended as the transfer from the primary registers to the secondary registers are done as a 16-bit word transfer.

For most MPWMSM operations, 16-bit accesses are sufficient and long word accesses (32-bit) are treated as two 16-bit accesses, with one exception — a long word write to the period/pulse width registers. In this case, if the long word write takes place within the PWM period, there is no visible effect on the output signal and the new values stored in MPWMPERR and MPWMPULR are ready to be loaded into the buffer registers at the start of the next period. If, however, the long word write coincides with the end of the period, then the transfer of values from the primary to the secondary registers is delayed until the end of the next period; during this period the previous values are used for the period and width. This feature enables updates of the period and pulse-width values without getting erroneous pulses.

## 17.10.4 Modular Input/Output Bus (MIOS14) Interface

The MPWMSM is connected to all the signals in the read/write and control bus, to allow data transfer from and to the MPWMSM registers, and to control the MPWMSM in the different possible situations.

- The MPWMSM is not using any of the 16-bit counter buses.
- The MPWMSM uses the request bus to transmit to the request submodule.

### 17.10.5 Effect of RESET on MPWMSM

The MPWMSM is affected by reset according to what is described in the section related to register description.

The MPWMPERR, MPWMPULR, and MPWMCNTR registers, together with the clock prescaler register bits, must be initialized by software, since they are undefined after hardware reset.

A value must be written to the MPWMCNTR (which writes the same value into the MPWMPERR) and a pulse width value written to MPWMPULR, before the MPWMSCR is written to. The latter access initializes the clock prescaler.

## 17.10.6 MPWMSM Registers

The privilege level to access to the MPWMSM registers depends on the MIOS14MCR[SUPV]. The privilege level is unrestricted after reset and can be change to supervisor by software.

### 17.10.6.1 MPWMSM Registers Organization

The MPWMSM register map comprises four 16-bit register locations, as shown in [Table 17-25](#). All unused bits return zero when read by the software. All register addresses in this section are specified as offsets from the base address of the MPWMSM.

**Table 17-25. MPWMSM Address Map**

| Address        | Register                                                                                           |

### 17.10.6.2 MPWMSM Period Register (MPWMPERR)

The period register contains the binary value corresponding to the period to be generated.

|                            |                                                                                                                                    |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

**Figure 17-27. MPWMSM Pulse Width Register (MPWMPULR)**

**Table 17-27. MPWMPULR Bit Descriptions**

| Bits | Name | Description                                                                          |
|------|------|--------------------------------------------------------------------------------------|
| 0:15 | PUL  | Pulse width. These bits contain the binary value of the pulse width to be generated. |

#### 17.10.6.4 MPWMSM Counter Register (MPWMCNTR)

The counter register reflects the actual value of the MPWMSM counter.

This register is writable only through the period register (PWMPERR). Writes to the counter register will write the same value to the period register.

|        |                                                                                                                                    |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

| Bits | Name | Description                                                         |
|------|------|---------------------------------------------------------------------|
| 0:15 | CNT  | Counter. These bits reflect the actual value of the MPWMSM counter. |

#### 17.10.6.5 MPWMSM Status/Control Register (MPWMSCR)

The status and control register gathers read only bits reflecting the status of the MPWMSM signal as well as read/write bits related to its control and configuration.

| MSB    |                                                                                                                                    |        |      |      |     |    |           |   |    |   |    |    |    |    | LSB |    |

### 17.11 MIOS14 16-bit Parallel Port I/O Submodule (MPIOSM)

The MIOS14 parallel port I/O submodule (MPIOSM) is a function included in the MIOS14 library in order to provide the required port I/O capability. The MPIOSM can operate without the involvement of other MIOS14 submodules.

Each implemented MPIOSM provides I/O capability for up to 16 signals.

The following sections describe the MPIOSM in detail. A block diagram of one bit of the MPIOSM is shown in [Figure 17-30](#). The MPIOSM contains 16 such blocks.

**Figure 17-30. MPIOSM 1-Bit Block Diagram**

### 17.11.1 MPIOSM Features

- A submodule of the MIOS14 library
- Uses two 16-bit registers in the address space
- Up to 16 bidirectional parallel input/output signals
- Simple DDR (data direction register) concept for signal direction selection

### 17.11.2 MPIOSM Signal Functions

Table 17-32 shows the MPIOSM I/O signal functions according to the setting of the DDR when writing to or reading from the DR.

**Table 17-32. MPIOSM I/O Signal Function**

| Operation Performed | DDR | I/O Signal Function                                                   |
|---------------------|-----|-----------------------------------------------------------------------|
| Write               | 0   | The I/O signal is in input mode. Data is written into the DR.         |
| Write               | 1   | Data is written into the DR and output to the I/O signal.             |
| Read                | 0   | The I/O signal is in input mode. The state of the I/O signal is read. |
| Read                | 1   | The I/O signal is in an output mode. The DR is read.                  |

### 17.11.3 MPIOSM Description

#### 17.11.3.1 MPIOSM Port Function

A MIOS14 parallel port I/O submodule can handle up to 16 input/output signals. The number of I/O signals is determined at the time of silicon implementation.

The MPIOSM has two 16-bit registers: the data register (DR) and the data direction register (DDR). Each signal of the MPIOSM may be programmed as an input or an output, determined by the state of the corresponding bit in the DDR.

The data direction register can be written to or read by the processor. During the programmed output state, a read of the data register reads the value of the output data latch and not the I/O signal. See [Figure 17-30](#) and [Table 17-32](#).

During reset, all MPIOSM signals are configured as inputs. The contents of the data register are undefined after reset.

As a general practice, it is recommended to write a value in the data register before configuring its corresponding I/O signal as an output.

#### 17.11.3.2 Non-Bonded MPIOSM Pads

A non-bonded MPIOSM pad reads '0' when it is configured as an input. When configured as an output, it indicates the current state of the output data latch.

### 17.11.4 Modular I/O Bus (MIOB) Interface

- The MPIOSM is connected to all the signals in the read/write and control bus, to allow data transfer from and to the MPIOSM registers, and to control the MPIOSM in the different possible situations.
- The MPIOSM does not use the counter bus set and is therefore not connected to it.
- The MPIOSM does not generate any interrupts and is therefore not connected to this bus.

### 17.11.5 Effect of RESET on MPIOSM

When the RESET signal is asserted, all the DDR bits are cleared. The data bits are undefined after reset.

### 17.11.6 MPIOSM Testing

No special test logic has been implemented in this submodule. To be flexible while selecting the number of implemented signals, the test patterns are implemented in a bit per bit modular fashion.

### 17.11.7 MPIOSM Registers

The privilege level to access to the MPIOSM registers depends on the MIOS14MCR[SUPV]. The privilege level is unrestricted after reset and can be change to supervisor by software.

### 17.11.8 MPIOSM Register Organization

|           | MSB                                        | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | LSB |

## 17.12 MIOS14 Interrupts

This section describes the interrupt functions of the MIOS14 and its submodules and how these interrupts are passed to the CPU via the peripheral bus. Interrupt requests from the MIOS14 are treated as exceptions by the CPU and are dealt with by the CPU’s exception processing routines. For a more detailed description of exception processing in the relevant microprocessors, please refer [Chapter 3, “Central Processing Unit”](#) and to the *RCPU Reference Manual*.

### 17.12.1 MIOS14 Interrupt Structure

The MIOS14 and its submodules are capable of generating interrupts on different levels to be transmitted to the CPU via the peripheral bus. Inside the MIOS14, all the information required for requesting and servicing the interrupts are treated in two different sections:

- The interrupt request submodules (MIRSM)
- The interrupt control section (ICS) of the MBISM

The MIRSM gathers in service request flags from each group of up to 16 submodules and transfers those requests to the MIOS14 interrupt control section (ICS). [Figure 17-34](#) shows a block diagram of the whole interrupt architecture.

NOTE: Submodules 9, 10, 25, and 26 are reserved on the MPC561, MPC562, MPC563, and MPC564.

**Figure 17-34. MIOS14 Interrupt Structure**

### 17.12.2 MIOS14 Interrupt Request Submodule (MIRSM)

Each submodule that is capable of generating an interrupt can assert a flag line when an event occurs. On MPC561/MPC563 each MIRSM serves 14 submodules.

Each MIRSM includes:

- One 16-bit status register (for the flags)
- One 16-bit enable register for each implemented level
- One 16-bit IRQ pending register for each implemented level

One bit position in each of the above registers is associated with one submodule.

**NOTE**

If a submodule in a group of 16 cannot generate interrupts, then its corresponding flag bit in the status register is inactive and is read as zero.

When an event occurs in a submodule that activates a flag line, the corresponding flag bit in the status register is set. The status register is read/write, but a flag bit can be reset only if it has previously been read as a one. Writing a “one” to a flag bit has no effect. When the software intends to clear only one flag bit within a status register, the software must write an all-ones 16-bit value except for the bit position to be cleared which is a zero.

The enable register is initialized by the software to indicate whether each interrupt request is enabled for the levels defined in the ICS.

**NOTE**

In the case of multiple requests levels implementation in the same MIOS14, it is possible to enable interrupts at more than one different levels for the same submodule. It is the responsibility of the software to manage this.

Each bit in the IRQ pending register is the result of a logical “AND” between the corresponding bits in the status and in the enable registers. If a flag bit is set and the level enable bit is also set, then the IRQ pending bit is set, and the information is transferred to the interrupt control section that is in charge of sending the corresponding level to the CPU. The IRQ pending register is read only.

**NOTE**

When the enable bit is not set for a particular submodule, the corresponding status register bit is still set when the corresponding flag is set. This allows the traditional software approach of polling the flag bits to see which ones are set. The status register makes flag polling easy, since up to 16 flag bits are contained in one register.

The submodule number of an interrupting source defines the corresponding MIRSM number and the bit position in the status registers. To find the MIRSM number and bit position of an interrupting source, proceed as follow:

1. Divide the interrupting submodule number by 16
2. The integer result of the division gives the MIRSM number
3. The remainder of the division gives the bit position

### 17.12.3 MIRSM0 Interrupt Registers

#### 17.12.3.1 Interrupt Status Register (MIOS14SR0)

This register contains the flag bits that are raised when the submodules generate an interrupt. Each bit corresponds to a given submodule.

**Figure 17-35. Interrupt Status Register (MIOS14SR0)**

**Table 17-35. MIOS14SR0 Bit Description**

| Bits  | Name     | Description                         |
|-------|----------|-------------------------------------|
| 0:4   | FLG15:11 | Flag Bits — MDASM flag bits [15:11] |
| 5:6   | —        | Reserved                            |
| 7:9   | FLG8:6   | Flag Bits — MMCSM flag bits [8:6]   |
| 10:15 | FLG5:0   | Flag Bits — PWMSM flag bits [5:0]   |

### 17.12.3.2 Interrupt Enable Register (MIOS14ER0)

This register contains the interrupt enable bits for the submodules. Each bit corresponds to a given submodule.

**Figure 17-36. Interrupt Enable Register (MIOS14ER0)**

**Table 17-36. MIOS14ER0 Bit Descriptions**

| Bits  | Name    | Description                             |
|-------|---------|-----------------------------------------|
| 0:4   | EN15:11 | Enable Bits — MDASM enable bits [15:11] |
| 5:6   | —       | Reserved                                |
| 7:9   | EN8:6   | Enable Bits — MMCSM enable bits [8:6]   |
| 10:15 | EN5:0   | Enable Bits — PWMSM enable bits [5:0]   |

### 17.12.3.3 Interrupt Request Pending Register (MIOS14RPR0)

This register is a read only register that contains the interrupt pending bits for the submodules. Each bit corresponds to a given submodule. When one of these bits is set, it means that a submodule raised its flag and the corresponding enable was set.

As this register is read only, a write to this register has no other effect than generating a bus error if the bus error option is selected.

## 17.12.4 MIRSM1 Interrupt Registers

### 17.12.4.1 Interrupt Status Register (MIOS14SR1)

This register contains the flag bits that are raised when the submodules generate an interrupt. Each bit corresponds to a given submodule.

| MSB    |                     |           |           |           |           |   |   |           |           |           |           |           |           |           | LSB       |           |
|--------|---------------------|-----------|-----------|-----------|-----------|---|---|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|

### 17.12.4.3 Interrupt Request Pending Register (MIOS14RPR1)

This register is a read only register that contains the interrupt pending bits for the submodules. Each bit corresponds to a given submodule. When one of these bits is set, it means that a submodule raised its flag and the corresponding enable was set.

As this register is read only, a write to this register has no other effect than generating a bus error if the bus error option is selected.

### 17.12.5 Interrupt Control Section (ICS)

The interrupt control section delivers the interrupt level to the CPU. The interrupt control section adapts the characteristics of the MIOB request bus to the characteristics of the interrupt structure of the IMB3.

When at least one of the flags is set on an enabled level, the ICS receives a signal from the corresponding IRQ pending register. This signal is the result of a logical “OR” between all the bits of the IRQ pending register.

The signal received from the IRQ pending register is associated with the interrupt level register within the ICS. This level is coded on five bits in this register: three bits represent one of eight levels and the two other represent the four time multiplex slots. According to this level, the ICS sets the correct  $\overline{\text{IRQ}}[7:0]$  lines with the correct ILBS[1:0] time multiplex lines on the peripheral bus. The CPU is then informed as to which of the thirty-two interrupt levels is requested.

Based on the interrupt level requested, the software must determine which submodule requested the interrupt. The software may use a find-first-one type of instruction to determine, in the concerned MIRSM, which of the bits is set. The CPU can then serve the requested interrupt.

### 17.12.6 MBISM Interrupt Registers

Table 17-41 shows the MBISM interrupt registers.

**Table 17-41. MBISM Interrupt Registers Address Map**

| Address   | Register                                                                                |

## 17.13 MIOS14 Function Examples

The versatility of the MIOS14 timer architecture is based on multiple counters and capture/compare channel units interconnected on 16-bit counter buses. This section includes some typical application examples to show how the submodules can be interconnected to form timing functions. The diagrams used to illustrate these examples show only the blocks utilized for that function.

To illustrate the timing range of the MIOS14 in different applications, many of the following paragraphs include time intervals quoted in microseconds and seconds. The assumptions used are that  $f_{SYS}$  is at 40 MHz with minimum overall prescaling (50 ns cycle) and with the maximum overall prescaling (32  $\mu$ s cycle). For other  $f_{SYS}$  clock cycle rates and prescaler choices, the times mentioned in these paragraphs scale appropriately.

### 17.13.1 MIOS14 Input Double Edge Pulse Width Measurement

To measure the width of an input pulse, the MIOS14 double action submodule (MDASM) has two capture registers so that only one interrupt is needed after the second edge. The software can read both edge

samples and subtract them to get the pulse width. The leading edge sample is double latched so that the software has the time of one full period of the input signal to read the samples to be sure that nothing is lost. Depending on the prescaler divide ratio, pulse width from 50 ns to 6.7 s can be measured. Note that a software option is provided to also generate an interrupt after the first edge.

In the example shown in Figure 17-43, a counter submodule is used as the time-base for a MDASM configured in the input pulse width measurement mode. When the leading edge (programmed for being either rising or falling) of the input signal occurs, the state of the 16-bit counter bus is saved in register B1. When the trailing edge occurs, the 16-bit counter bus is latched into register A and the content of register B1 is transferred to register B2. This operation leaves register B1 free for the next leading edge to occur on the next clock cycle. When enabled, an interrupt is provided after the trailing edge, to notify the software that pulse width measurement data is available for a new pulse. After the trailing edge, the software has one cycle time of the input signal to obtain the values for each edge. When software attention is not needed for every pulse, the interrupt can be disabled. The software can read registers A and B2 coherently (using a 32-bit read instruction) at any time, to get the latest edge measurements. The software work is less than half that needed with a timer that requires the software to read one edge and save the value and then wait for the second edge.

Figure 17-43. MIOS14 Example: Double Capture Pulse Width Measurement

### 17.13.2 MIOS14 Input Double Edge Period Measurement

Two samples are available to the software from an MIOS14 double action submodule for period measurement. The software can read the previous and the current edge samples and subtract them. As with pulse width measurement, the software can be sure not to miss samples by ensuring that the interrupt response time is faster than the fastest input period. Alternately, when the software is just interested in the latest period measurement, one 32-bit coherent read instruction can get both the current and the previous samples. Depending on the prescaler divide ratio, period times can be measured from 50 ns to 6.7 s.

Figure 17-44 shows a counter submodule and a DASM combination as an example of period measurement. The software designates whether the rising or falling edge of the input signal is to be used for the measurements. When the edge is detected, the state of the 16-bit counter bus is stored in register A and the content of register B1 is transferred to register B2. After register B2 is safely latched, the content of register A is transferred to register B1. This procedure gives the software coherent current and previous samples in registers A and B2 at all times. An interrupt is available for the cases where the software needs to be aware of each new sample. Note that a software option is provided to also generate an interrupt after the first edge.

Figure 17-44. MIOS14 Example: Double Capture Period Measurement

### 17.13.3 MIOS14 Double Edge Single Output Pulse Generation

Software can initialize the MIOS14 to generate both the rising and the falling edge of an output pulse. With a MDASM, pulses as narrow as 50 ns can be generated since software action is not needed between the edges. Pulses as long as 2.1 s can be generated. When an interrupt is desired, it can be selected to occur on every edge or only after the second edge.

Figure 17-45 shows how a counter submodule and a MDASM can be used to generate both edges of a single output pulse. The software puts the compare value for one edge in register A and the other one in register B2. The MDASM automatically creates both edges and the pulse can be selected by software to be a high-going or a low-going. After the trailing edge, the MDASM stops to await further commands from the software. Note that a single edge output can be generated by writing to only one register.

Figure 17-45. MIOS14 Example: Double Edge Output Compare

#### 17.13.4 MIOS14 Output Pulse Width Modulation with MDASM

Output waveforms can be generated with any duty cycle without software involvement. The software sets up a MDASM with the compare times for the rising and falling edges and they are automatically repeated. The software does not need to respond to interrupts to generate continuous pulses. The frequency may be selected as the frequency of a free-running counter time-base, times a binary multiplier selected in the MDASM. Multiple PWM outputs can be created from multiple MDASMs and share one counter submodule, provided that the frequencies of all of the output signals are a binary multiple of the time-base and that the counter submodule is operating in a free-running mode. Each MDASM has a software selectable “don’t care” on high-order bits of the time-base comparison so that the frequency of one output can be a binary multiple of another signal. Masking the time-base serves to multiply the frequency of the time-base by a binary number to form the frequency of the output waveform. The duty cycle can vary from one cycle to 64-Kbyte cycles. The frequency can range from 0.48 Hz to 156 KHz, though the resolution decreases at the higher frequencies to as low as seven bits. The generation of output square wave signals is of course the special case where the high and low times are equal.

When an MMCSM is used to drive the time-base, the modulus value is the period of the output PWM signal. Figure 17-46 shows such an example. The polarity of the leading edge of an output waveform is programmable for a rising or a falling edge. The software selects the period of the output signal by programming the MMCSM with a modulus value. The leading edge compare value is written into register A by software and the trailing edge time is written into register B1. When the leading edge value is reached, the content of register B1 is transferred to register B2, to form the next trailing edge value. Subsequent changes to the output pulse width are made by writing a new time into register B1. Updates to the pulse width are always synchronized to the leading edge of the waveform.

It is typical to use the pulse width modulation mode of the MDASM without interrupts, although an interrupt can be enabled to occur on the leading edge. When the output is an unchanging repetitive waveform, the MDASM continuously generates the signal without any software intervention. When the software needs to change the pulse width, a new trailing edge time is written to the MDASM. The output is changed on the next full pulse. When the software needs to change the output at a regular rate, such as an acceleration curve, the leading edge interrupt gives the software one period time to update the new trailing edge time.

Figure 17-46. MIOS14 Example: Pulse Width Modulation Output

### 17.13.5 MIOS14 Input Pulse Accumulation

Counting the number of pulses on an input signal is another capability of the MIOS14. Pulse accumulation uses an MMCSM. Since the counters in the counter submodules are software accessible, pulse accumulation does not require the use of an action submodule. The pulse accumulation can operate continuously, interrupting only on binary overflow of the 16-bit counter. When an MMCSM is used, an interrupt can instead be created when the pulse accumulation reaches a preprogrammed value. To do that, the two's complement of the value is put in the modulus register and the interrupt occurs when the counter overflows.

## Chapter 18

# Peripheral Pin Multiplexing (PPM) Module

The peripheral pin multiplexing (PPM) module has two main functions. The first function allows the PPM to act as a parallel-to-serial communications module. Using the PPM in this way can reduce the number of signals required to connect the MPC561/MPC563 to an external device or devices. The second function allows the PPM to short internal signals thus giving increased access to multiple functions multiplexed on the same device signal. See [Figure 18-1](#) for a comparison of the MPC555 N-Signal I/O and the MPC561/MPC563 PPM I/O.

### 18.1 Key Features

- Synchronous serial interface between MCU and an external device
- Four internal parallel data sources can be multiplexed through the PPM
  - TPU3\_A: 16 channels
  - TPU3\_B: 16 channels
  - MIO5: 12 PWM channels, four MDA channels
  - Internal GPIO: 16 general-purpose inputs, 16 general-purpose outputs
- Software configurable stream size
  - One 16-bit transmit stream and one 16-bit receive stream
  - Two parallel 8-bit transmit streams and two parallel 8-bit receive streams
- Software configurable clock (PPM\_TCLK) based on system clock
- Software selectable clock modes
  - Serial peripheral interface (SPI) mode
  - Time division multiplexing (TDM) mode
- Software selectable operation modes
  - Continuous mode – Continuously transmit/receive data through PPM
  - Start-transmit-receive (STR) mode – transmit/receive only when STR mode selected
- Software configurable internal module shorting of the following signals:
  - TouCAN\_A[A\_CNRX0, A\_CNTX0] to TouCAN\_B[B\_CNRX0, B\_CNTX0] and/or TouCAN\_C[C\_CNRX0, C\_CNTX0]
  - TouCAN\_B[B\_CNRX0, B\_CNTX0] to TouCAN\_C[C\_CNRX0, C\_CNTX0]
  - A\_TPUCH0 to B\_TPUCH0
  - A\_TPUCH1 to B\_TPUCH1
  - A\_TPUCH15 to ETRIG1
  - B\_TPUCH15 to ETRIG2

— A\_T2CLK to B\_T2CLK

Figure 18-1. N-Signal I/O Compared with PPM I/O

## 18.2 Programming Model

The PPM occupies 100 bytes of address space, arranged as 50 16-bit entries. All registers must be read or written through half-word (16-bit) accesses. Reserved register addresses return zeros when read and cannot be written to. [Table 18-1](#) shows the memory map for the PPM module.

Table 18-1. PPM Memory Map

<sup>1</sup> Only accessible in Supervisor Mode.

<sup>2</sup> This register is accessible in Test Mode only. Reads/Writes to this register when not in Test Mode will return  $\overline{TEA}$  (bus error access).

<sup>3</sup> Accessible in Supervisor Mode and User Mode (when PPMCR[SUPV]=0).

## 18.3 Functional Description

In order to reduce the number of signals on the devices, many signals have multiple functions and each signal must be configured for access to any of these functions. The PPM module is designed to increase the availability of MPC561/MPC563 signal multiplexed functions. It can do this in two ways:

- By implementing a parallel-to-serial communication protocol,
- By implementing internal signal shorting.

### 18.3.1 PPM Parallel-to-Serial Communication Protocol

The PPM communication sub-modules, PPM\_MUX and PPM\_SHIFTER, transfer data between the MPC561/MPC563 and external devices. The PPM reduces the number of connections between devices by allowing certain internal modules of the MCU to transmit and receive data serially, where without PPM those internal modules would have to transmit and receive data in parallel. Data is routed through the PPM using internal multiplexers. Communication between the internal modules and the PPM remains a parallel connection, but the PPM connects to external devices by a serial link. The PPM can be configured for different data transfer rates and data formats.

**Figure 18-2. Block Diagram of PPM Module**

## 18.3.1.1 Internal Multiplexing

In the MPC561/MPC563 devices, the PPM module supports multiplexing of four modules: TPU3\_A, TPU3\_B, MIOS and GPIO registers, internal to the PPM. Internal multiplexers route data between the MCU internal modules and the external device through the PPM. Four configuration registers, TX\_CONFIG\_1, TX\_CONFIG\_2, RX\_CONFIG\_1 and RX\_CONFIG\_2, control these internal multiplexers. By programming the configuration registers the PPM multiplexers select which internal module will drive data out of the PPM and which will receive data from the PPM.

The TX\_CONFIG and RX\_CONFIG registers allocate two bits to control each of the 16 internal multiplexers. During transmit operations, the TX\_CONFIG registers determine which internal module's data will be sampled and routed to the transmit sample-and-shift register, TX\_DATA. During receive operations, data in the receive sample-and-shift register, RX\_SHIFTER, is routed to the internal module specified by the value of the RX\_CONFIG registers, or in the case where GPDI is the destination, data is routed directly from PPM\_RX[0:1]. Refer to [Figure 18-4](#).

**Figure 18-3. Internal Multiplexer Mechanism for Transmit Data**

**Figure 18-4. Internal Multiplexer Mechanism for Received Data**

### 18.3.1.2 PPM Clocks

The PPM module generates and outputs two clock signals, PPM\_TCLK and PPM\_TSYNC. The PPM\_TCLK and PPM\_TSYNC clocks are the basis for all PPM communication functions; single data bits are transmitted and received on PPM\_TCLK cycles, one PPM\_TSYNC clock cycle defines a single 16-bit word transmit/receive cycle. The PPM can be configured to transfer data in one of two clock modes, SPI and TDM. [Figure 18-5](#) shows examples of PPM\_TCLK in SPI and TDM modes. The frequency of PPM\_TCLK is a function of the system clock (SYSCLK) and is programmable using the

SCALE\_TCLK\_REG. The transmit signals, PPM\_TX, will stay high as long as PPM\_TSYNC is high (equal to “1” in [Figure 18-5](#)).

**Figure 18-5. PPM Clocks and Serial Data Signals**

Complete transmit and receive cycles are based on the PPM\_TSYNC clock. A cycle begins on the rising edge of PPM\_TSYNC, which goes high for one PPM\_TCLK cycle. The transmit signals, PPM\_TX[0:1], will stay high as long as PPM\_TSYNC is high (equal to “1” in [Figure 18-6](#)). Data bits start to transmit on the falling edge of PPM\_TSYNC. In receive mode, valid data starts to shift into RX\_SHIFTER on the falling edge of PPM\_TSYNC. PPM\_TSYNC stays low until the contents of TX\_DATA have been shifted out and/or 16 bits have been shifted into RX\_SHIFTER. One data bit is transferred every PPM\_TCLK cycle.

Figure 18-6. One Transmit and Receive Cycle in SPI Mode

### 18.3.1.3 PPM Control Settings

As data is transferred through the PPM module it must be sampled at a rate which guarantees its validity. This sample rate is a multiple of PPM\_TCLK and is defined by the SAMP[0:2] field of the PPMPCR register. For transmit operations, the sample rate is the rate at which TX\_DATA receives data from the internal modules. For receive operations, it is the rate at which the internal modules read RX\_SHIFTER. The register RX\_DATA is updated from RX\_SHIFTER on completed receive (PPM\_TSYNC) cycles.

PPM\_TCLK(1) = SYSCLK/4

Update(1) every PPM\_TCLK(1) clock

PPM\_TCLK(2) = SYSCLK/2

Update(2) every PPM\_TCLK(2) clock

Update(3) every second PPM\_TCLK(2) clock

Update(4) every fourth PPM\_TCLK(2) clock

**Figure 18-7. Examples Of Several TCLK Frequencies and Sample Rates**

The PPM Module has two data transmit signals, PPM\_TX[0:1], and two data receive signals, PPM\_RX[0:1]. The amount of data transferred on these signals depends on the setting in PPMPCR[OP\_16\_8]. If the PPM is configured to transfer data in 16 PPM\_TCLK cycles per 16-bit word then all data in TX\_DATA[0:15] is transmitted on the PPM\_TX0 signal, and all data is received into RX\_SHIFTER[0:15] from PPM\_RX0. If the PPM is configured to transfer data in eight PPM\_TCLK cycles per 16-bit word then the eight bits will transfer on each of the data transfer signals.

### NOTE

Care must be taken when setting the sample rate with respect to the OP\_16\_8 bit setting. For example if the PPM is transferring data on an 8-clock cycle, then setting the sample rate to every 16 clocks will result in lost data.

In SPI mode the phase and polarity of PPM\_TCLK is selectable by programming bits in the PPMPCR register. PPM\_TCLK can have normal polarity (active high) or inverted polarity (active low). There are two clock phases available: valid data can be latched on the transition of PPM\_TCLK from its active edge to inactive edge, or valid data can be latched on the transition of PPM\_TCLK from its inactive edge to active edge.

See [Section 18.4.2, “PPM Control Register \(PPMPCR\)”](#) for more information on SPI mode PPM\_TCLK settings.

## 18.3.2 PPM Signal Short Functionality

The MPC561/MPC563 devices have many modules that multiplex their functions onto shared signals. In order to access those functions, the signals must be configured appropriately. However, choosing one function can be at the cost of another function. The PPM makes more functions available simultaneously by creating internal shorts that can activate functions that would otherwise require an external signal. Internal signal shorts are enabled using the PPM short register, `SHORT_REG`.

### 18.3.2.1 TouCAN Shorting

There are three TouCAN modules on the MPC561/MPC563 devices. Using the PPM it is possible to internally short the `CNRX0` and `CNTX0` signals of these three modules to increase message buffer capacity. Three bits of the `SHORT_REG` register (`SH_TCAN[0:2]`), are allocated to enable four combinations of shorting between the TouCAN modules. See [Table 18-8](#) for information on these bit descriptions.

When one TouCAN module is shorted to another, the `CANRX` signals and the `CANTX` signals of both modules are shorted internally. Both modules continue to operate as normal but all transmit and receive operations are done using only one pair of `CANRX` and `CANTX` signals. The `CANRX` and `CANTX` signals of the other module are no longer under the control of the TouCAN module.

The C\_TouCAN signals `C_CNTX0` and `C_CNRX0` are multiplexed signals. When C\_TouCAN is shorted with one or two other TouCAN modules, C\_TouCAN no longer has control of these signals and so they can be configured for another of the available functions. Refer to [Chapter 2, “Signal Descriptions,”](#) for more information. Also see [Figure 18-24](#).

### 18.3.2.2 TPU Shorting

There are two TPU3 modules on the MPC561/MPC563 devices. Using the PPM, it is possible to internally short channel `A_TPUCH0` with `B_TPUCH0` and channel `A_TPUCH1` with `B_TPUCH1`. Two bits of the `SHORT_CH` register (`SH_TPU[1:0]`) control the internal shorting. The input/output enable states of the TPU channels themselves determine the effect that the short bits have on the TPU modules' operation. See [Table 18-9](#) for information on `SHORT_CH[SH_TPU]` bit descriptions.

The PPM only controls the internal shorting of TPU3 channels `TPUCH0` and `TPUCH1`. TPU channels are configured for input and output by the TPU ROM functions defined for them. Refer to [Appendix D, “TPU3 ROM Functions”](#) for further information, and see [Figure 18-25](#). If `TPU_A` and `TPU_B` channel 0 are shorted via `SHORT_CH[SH_TPU]` and one is set to output while the other is set to input, then the data from the output channel will not appear on the pin of the input channel. This holds true if `TPU_A` and `TPU_B` channel 1 are shorted via `SHORT_CH[SH_TPU]`. Connect an external device to the pin of the module that has the channel function set to output.

### 18.3.2.3 ETRIG1 and ETRIG2

Each of the two QADC64E modules on the MPC561/MPC563 has an external trigger input signal that can be used to trigger analog to digital conversions. Using the PPM, these external trigger inputs can be sourced internally. Control for these short functions is found in `SHORT_REG[SH_ET1]` and

SHORT\_REG[SH\_ET2]. ETRIG1 can be shorted to A\_TPUCH15 and ETRIG2 can be shorted to B\_TPUCH15.

Since the ETRIG1 and ETRIG2 signals are shared with PCS6 and PCS7 respectively, the PPM shorting will allow both ETRIG and PCS functions to be available. By setting up A\_TPUCH15 and/or B\_TPUCH15 as output signals, enabling a short to ETRIG1 and/or ETRIG2 and sending a trigger signal from the TPU channels, the QADC64E can be successfully triggered, leaving the ETRIG signals free to be configured for PCS functions.

### 18.3.2.4 T2CLK

Each of the two TPU modules has an input clock, T2CLK. The A\_T2CLK and B\_T2CLK signals are shared with PCS4 and PCS5 respectively. The T2CLK signals can be shorted internally by SHORT\_REG[SH\_T2CLK] so that only one signal needs to be input to the device, leaving the other signal free for PCS functionality.

### 18.3.3 PPM Module Pad Configuration

The PPM module has six pads associated with it, four I/O pads PPM\_RX[0:1] and PPM\_TX[0:1] and two clock outputs PPM\_TCLK and PPM\_TSYNC. All six PPM signals are multiplexed with MIOS signals. In order to be able to access the PPM functions the signals must be configured appropriately. PPM pad control is done in the PDMCR2 register.

As well as enabling signal functions, this register can configure the PPM pads for 2.6-V or 5-V operation. Refer to [Chapter 2, “Signal Descriptions,”](#) for more details.

## 18.4 PPM Registers

### 18.4.1.1 Entering Stop Mode

The PPM module cannot, and should not, be put into stop mode while either the transmit or receive operation is enabled in PPMPCR[ENTX] and/or PPMPCR[ENRX]. Furthermore, it should not be put into stop mode if it is operating in continuous mode. In this case it should be switched to single transfer mode first.

The following steps should be taken to ensure that stop mode is entered safely and without loss of data:

1. If the PPM is operating in continuous mode
  - switch to single transfer mode by clearing PPMPCR[CM]=0.
2. If the PPM is enabled for transmit or receive
  - set PPMPCR[STR] (TDM or SPI mode)
  - Disable both PPMPCR[ENTX] and PPMPCR[ENRX]
  - Wait until PPMPCR[STR] is cleared by the PPM module. This will be done when the next data frame has been sent or received.
3. If the PPM is not enabled for transmit or receive
  - Clear PPMPCR[STR] if necessary
4. Set PPMMCR[STOP]
 

When PPMMCR[STOP] is set, the PPM module enters stop mode and the PPM module clocks will be stopped. While in stop mode, none of the PPM registers will be accessible, except for the PPMPCR register.

If the STOP bit is clear, stop mode is disabled.

| 6    | SPI               | SPI mode enable.<br>0 TDM mode enabled<br>1 SPI mode enabled                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 7    | STR               | Start-Transmit-Receive bit. When this bit is set and SPI mode is enabled, the PPM module will start to transmit and/or receive one frame of data. The STR bit will then be cleared automatically by the PPM. Refer to <a href="#">Table 18-5</a> .<br>0 PPM has completed transmitting and/or receiving one data frame.<br>1 PPM will transmit and/or receive one data frame.                                                                                                             |
| 8    | CI                | Clock Invert. This bit defines the polarity of TCLK clock in both SPI and TDM modes.<br>0 Normal clock polarity – active high clocks selected<br>1 Inverted clock – active low clocks selected                                                                                                                                                                                                                                                                                            |
| 9    | CP                | Clock Phase. This bit selects one of two fundamentally different transfer formats. Refer to figures <a href="#">Figure 18-12</a> and <a href="#">Figure 18-13</a> .<br>0 Valid data can be latched on the transition of TCLK from inactive phase to active phase.<br>1 Valid data can be latched on the transition of TCLK from active phase to inactive phase.                                                                                                                           |

**Table 18-3. PPMPCR Bit Descriptions (continued)**

| Bits  | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-------|------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 10    | CM   | <p>Continuous Mode.</p> <p>0 Non-continuous mode (default). Transmit and/or receive one data frame when STR = 1. (STR will be automatically cleared by the PPM after the transfer of one data frame.)</p> <p>1 Data will continuously be transmitted and/or received as long as Transmit and Receive are enabled.</p> <p>Refer to <a href="#">Table 18-5</a> for more information.</p> <p><b>Note:</b> Ensure PPMPCR[STR]=0 when setting PPMPCR[CM]=1</p> |
| 11:15 | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

<sup>1</sup> Enable RX.

(a) If ENRX is disabled, no data will shift into the PPM.

(b) If ENRX is asserted while ENTX=1, the first data bit received will be the data that is transmitted from the PPM, and not RX0. See [Figure 18-10](#). To receive the first data frame correctly, ENRX and ENTX should be set simultaneously.

<sup>2</sup> Enable TX.

(a) If ENTX is disabled, no data will shift out of the PPM and the PPM output signals, PPM\_TX0 and PPM\_TX1 will be high.

(b) If ENTX is asserted while ENRX = 1, the first data bits transmitted out of the PPM will be the data that was received into the PPM. See [Figure 18-11](#). To transmit the first data frame correctly, set ENTX and ENRX simultaneously.

**Table 18-4. SAMP[0:2] Bit Settings**

| SAMP[0:2] | Sample Rate   |
|-----------|---------------|
| 000       | Every TCLK    |
| 001       | Every 2 TCLK  |
| 010       | Every 4 TCLK  |
| 011       | Every 8 TCLK  |
| 100 – 111 | Every 16 TCLK |

Table 18-5. PPMPCR[CM] and PPMPCR[STR] Bit Operation

| PPMPCR[CM] | PPMPCR[STR] | Result                                                                                                                                                                             |
|------------|-------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0          | 1           | One data frame transmitted and/or received through PPM.                                                                                                                            |
| 0          | 0           | Transfer of one data frame completed.                                                                                                                                              |
| 1          | X           | Continuously transmit and/or receive data frames through PPM.                                                                                                                      |
| X          | X           | CM and STR will only effect PPM transmit/receive when PPM is configured for SPI mode. In TDM mode transmit/receive will be continuous regardless of the values of CM and STR bits. |

### 18.4.3 Transmit Configuration Registers (TX\_CONFIG\_1 and TX\_CONFIG\_2)

The two transmit configuration registers control which internal modules will transmit data through the PPM. Each of the configuration registers contains eight separate 2-bit wide bit fields. Each of the 16 fields controls a multiplexer that selects a 1-bit channel from an internal module to the PPM transmit data register. See [Table 18-6](#) for more information on channel control and setting the channel values.

TX\_CONFIG\_1 and TX\_CONFIG\_2 can only be written while PPM transmit mode is disabled (PPMPPCR[ENTX] = 0). While transmit is enabled these registers read as 0x00 and writing them will return TEA (bus error access).

Figure 18-15. Transmit Configuration Register 2 (TX\_CONFIG\_2)

#### 18.4.4 Receive Configuration Registers (RX\_CONFIG\_1 and RX\_CONFIG\_2)

The two receive configuration registers control which internal modules will receive data from the PPM. Each of the configuration registers contains eight separate 2-bit wide bit fields. Each of the 16 fields controls a multiplexer that selects a 1-bit channel from the PPM data receive register to an internal module. See [Table 18-6](#) for more information on channel control and setting the channel values.

RX\_CONFIG\_1 and RX\_CONFIG\_2 can only be written while PPM receive mode is disabled (PPMPPCR[ENRX] = 0). While receive mode is enabled these registers read as 0x00 and writing them will return TEA (bus error access).

## 18.4.5 Receive Data Register (RX\_DATA)

RX\_DATA receives data from the RX\_SHIFTER register. It is updated from RX\_SHIFTER at the end of a receive cycle (i.e., rising edge of PPM\_TSYNC).

|                            |                     |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|----------------------------|---------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|
|                            | MSB                 | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |

| Addr                       | 0x30 5C16           |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

Figure 18-18. Receive Data Register (RX\_DATA)

### 18.4.6 Receive Shift Register (RX\_SHIFTER)

RX\_SHIFTER receives data serially from the PPM input signals PPM\_RX[0:1] (depending on the value of PPMPCR[OP\_16\_8]). Data bits are shifted in on every PPM\_TCLK cycle. Data in the RX\_SHIFTER register is delivered directly to the MPC561/MPC563 internal modules with no wait time.

|                            |                     |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|----------------------------|---------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|
|                            | MSB                 | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |

| $\overline{\text{SRESET}}$ | 0000_0000_0000_0000 |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
| Addr                       | 0x30 5C1A           |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

Figure 18-19. Receive Shifter Register (RX\_SHIFTER)

### 18.4.7 Transmit Data Register (TX\_DATA)

TX\_DATA contains data from the internally multiplexed modules that is to be transmitted from the PPM module on the PPM\_TX[1:0] signals (depending on the value in PPMPCR[OP\_16\_8]). Data bits are transmitted serially (shifted out) on each PPM\_TCLK cycle. The data is shifted out least significant bit (LSB) first, therefore TX\_DATA15 first, TX\_DATA0 last.

|                            |                     |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|----------------------------|---------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|
|                            | MSB                 | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | LSB |
| Field                      | TX_DATA             |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
| $\overline{\text{SRESET}}$ | 0000_0000_0000_0000 |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
| Addr                       | 0x30 5C1E           |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

Figure 18-20. Transmit Data Register (TX\_DATA)

### 18.4.8 General-Purpose Data Out (GPDO)

GPDO is an internal register whose data can be transmitted serially through the PPM. By default, the transmit configuration registers are set to transmit from this register. The value in GPDO[0:15] is written into TX\_DATA[0:15].

|        |                     |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|--------|---------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|

| Addr   | 0x30 5C22           |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |

Figure 18-21. General Purpose Data Out Register (GPDO)

### 18.4.9 General-Purpose Data In (GPDI)

GPDI is an internal register that receives data directly from the PPM input signals, PPM\_TX[0:1]. By default, the receive configuration registers are set to direct received data from RX\_DATA[0:15] to the GPDI[0:15] register.

|        |                     |   |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |     |
|--------|---------------------|---|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|-----|

Figure 18-22. General Purpose Data In Register (GPDI)

### 18.4.10 Short Register (SHORT\_REG)

SHORT\_REG allows the shorting of certain internal signals in the MPC561/MPC563 devices. This feature allows functions, whose internal signals are multiplexed on external signals, to be accessible simultaneously.

|        |                     |   |   |             |   |          |   |        |        |          |          |    |    |    |     |    |

| Bits | Name         | Description                                                                                                                                                                                                                                                                                                                                                               |
|------|--------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:2  | SH_TCAN[2:0] | Short TouCAN modules. These three bits determine which TouCAN modules are internally shorted. See <a href="#">Table 18-8</a> for a description of the effects of these bit settings.                                                                                                                                                                                      |
| 3:4  | SH_TPU[1:0]  | Short TPU3 modules. The channels A_TPUCH0 and B_TPUCH0 can be internally shorted by the SH_TPU0. Channels A_TPUCH1 and B_TPUCH1 can be internally shorted by SH_TPU1. The effect of the internal shorts depends on the input/output enable control for the TPU channels themselves. See <a href="#">Table 18-9</a> for more information on bit settings for TPU shorting. |

**Figure 18-25. Short Between TPU Channels**

### 18.4.11 Short Channels Register (SHORT\_CH\_REG)

SHORT\_CH\_REG allows the shorting of transmit channels from the PPM using the bit field SHORT[7:0]. The PPM normally transmits data by right-shifting TX\_DATA at the rate of one bit per PPM\_TCLK cycle, TX\_DATA15 first. Shorts can be enabled for transmit data bits TX\_DATA[1, 3, 5, 7, 9, 11, 13, and 15]. Where a short is enabled for any of these transmit data bits, that bit will be transmitted for two PPM\_TCLK cycles, during its own bit time and the bit time of the following transmit data bit.

#### EXAMPLE

If SHORT\_CH<sub>x</sub> = 1, transmit TX\_DATA<sub>x</sub> during TX\_DATA<sub>x</sub> bit time and repeat TX\_DATA<sub>x</sub> during TX\_DATA<sub>[x-1]</sub> bit time.

### 18.4.12 Scale Transmit Clock Register (SCALE\_TCLK\_REG)

SCALE\_TCLK\_REG is used to set the rate of the PPM\_TCLK that provides the timing for data transfer into and out of the PPM module. The PPM\_TCLK frequency is derived from the system clock, F<sub>SYSClk</sub>. PPM\_TCLK is software programmable using the following formula:

$$F_{PPM\_TCLK} = F_{SYSClk} / (2 * SCT[6:0])$$

The range of PPM\_TCLK frequencies available is:

Table 18-12. SCALE\_TCLK Frequencies

| Minimum                  | Maximum                |
|--------------------------|------------------------|
| F <sub>SYSClk</sub> /256 | F <sub>SYSClk</sub> /2 |

|        |                     |   |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |     |

| 9:15 | SCT[6:0] | Determines the frequency of PPM_TCLK.<br><ul style="list-style-type: none"> <li>SCT[6:0] = 0 F<sub>SYSClk</sub> / 256</li> <li>SCT[6:0] = 1 to 127 F<sub>SYSClk</sub> / (2 * SCT[6:0])</li> </ul> Writing to SCT[6:0] while the PPM is enabled will cause an irregular PPM cycle to occur. |

# Chapter 19

## Time Processor Unit 3

The time processor unit 3 (TPU3), an enhanced version of the original TPU, is an intelligent, semi-autonomous microcontroller designed for timing control. The TPU3 is fully compatible to the TPU2. Operating simultaneously with the CPU, the two TPU3 modules process micro-instructions, schedule and process real-time hardware events, perform input and output, and access shared data without CPU intervention. Consequently, for each timer event, the CPU setup and service times are minimized or eliminated.

The MPC561/MPC563 contains two independent TPU3s: TPU\_A and TPU\_B. These two TPU3 modules are memory mapped as shown in [Table 19-1](#).

**Table 19-1. TPU Memory Map**

| TPU   | Address             |
|-------|---------------------|
| TPU_A | 0x30 4000—0x30 43FF |
| TPU_B | 0x30 4400—0x30 47FF |

[Figure 19-1](#) is a simplified block diagram of a single TPU3.

**Figure 19-1. TPU3 Block Diagram**

## 19.1 Overview

The TPU3 can be viewed as a special-purpose microcomputer that performs a programmable series of two operations, match and capture. Each occurrence of either operation is called an event. A programmed series of events is called a function. TPU functions replace software functions that would require CPU interrupt service.

The microcode ROM TPU3 functions that are available in the MPC561/MPC563 are described in [Appendix D, “TPU3 ROM Functions.”](#)

## 19.2 TPU3 Components

The TPU3 consists of two 16-bit time bases, 16 independent timer channels, a task scheduler, a microengine, and a host interface. In addition, a dual-ported parameter RAM (DPTRAM) is used to pass parameters between the module and the CPU.

### 19.2.1 Time Bases

Two 16-bit counters provide reference time bases for all output-compare and input-capture events. Prescalers for both time bases are controlled by the CPU via bit fields in the TPU3 module configuration register (TPUMCR) and TPU module configuration register two (TPUMCR2). Timer count registers TCR1 and TCR2 provide access to the current counter values. TCR1 and TCR2 can be read by TPU microcode but are not directly available to the CPU. The TCR1 clock is always derived from the system clock. The TCR2 clock can be derived from the system clock or from an external input via the T2CLK clock pin. The duration between active edges on the T2CLK clock pin must be at least nine system clocks.

### 19.2.2 Timer Channels

The TPU3 has 16 independent channels, each connected to an MCU pin. The channels have identical hardware and are functionally equivalent in operation. Each channel consists of an event register and pin control logic. The event register contains a 16-bit capture register, a 16-bit compare/match register, and a 16-bit greater-than-or-equal-to comparator. The direction of each pin, either output or input, is determined by the TPU microengine. Each channel can either use the same time base for match and capture, or can use one time base for match and the other for capture.

### 19.2.3 Scheduler

When a service request is received, the scheduler determines which TPU3 channel is serviced by the microengine. A channel can request service for one of four reasons: for host service, for a link to another channel, for a match event, or for a capture event. The host system assigns each active channel one of three priorities: high, middle, or low. When multiple service requests are received simultaneously, a priority-scheduling mechanism grants service based on channel number and assigned priority.

### 19.2.4 Microengine

The microengine is composed of a control store and an execution unit. Control-store ROM holds the microcode for each factory-masked time function. When assigned to a channel by the scheduler, the execution unit executes microcode for a function assigned to that channel by the CPU. Microcode can also be executed from the dual-port RAM (DPTRAM) module instead of the control store. The DPTRAM allows emulation and development of custom TPU microcode without the generation of a microcode ROM mask. Refer to [Section 19.3.6, “Emulation Support”](#) for more information.

### 19.2.5 Host Interface

The host interface registers allow communication between the CPU and the TPU3, both before and during execution of a time function. The registers are accessible from the IMB through the TPU3 bus interface unit. Refer to [Section 19.4, “Programming Model”](#) for register bit/field definitions and address mapping.

### 19.2.6 Parameter RAM

Parameter RAM occupies 256 bytes at the top of the system address map. Channel parameters are organized as 128 16-bit words. Channels zero through 15 each have eight parameters. The parameter RAM address map in [Section 19.4.15, “TPU3 Parameter RAM,”](#) shows how parameter words are organized in memory.

The CPU specifies function parameters by writing to the appropriate RAM address. The TPU3 reads the RAM to determine channel operation. The TPU3 can also store information to be read by the CPU in the parameter RAM. Detailed descriptions of the parameters required by each time function are beyond the scope of this manual. Refer to the *TPU Reference Manual* (TPURM/AD), included in the *TPU Literature Package* (TPULITPAK/D) for more information.

## 19.3 TPU Operation

All TPU3 functions are related to one of the two 16-bit time bases. Functions are synthesized by combining sequences of match events and capture events. Because the primitives are implemented in hardware, the TPU3 can determine precisely when a match or capture event occurs, and respond rapidly. An event register for each channel provides for simultaneous match/capture event occurrences on all channels.

When a match or input capture event requiring service occurs, the affected channel generates a service request to the scheduler. The scheduler determines the priority of the request and assigns the channel to the microengine at the first available time. The microengine performs the function defined by the content of the control store or emulation RAM, using parameters from the parameter RAM.

### 19.3.1 Event Timing

Match and capture events are handled by independent channel hardware. This provides an event accuracy of one time-base clock period, regardless of the number of channels that are active. An event normally causes a channel to request service. The time needed to respond to and service an event is determined by which channels and the number of channels requesting service, the relative priorities of the channels requesting service, and the microcode execution time of the active functions. Worst-case event service

time (latency) determines TPU3 performance in a given application. Latency can be closely estimated. For more information, refer to the *TPU Reference Manual* (TPURM/AD).

### 19.3.2 Channel Orthogonality

Most timer systems are limited by the fixed number of functions assigned to each pin. All TPU3 channels contain identical hardware and are functionally equivalent in operation, so that any channel can be configured to perform any time function. Any function can operate on the calling channel, and, under program control, on another channel determined by the program or by a parameter. The user controls the combination of time functions.

### 19.3.3 Interchannel Communication

The autonomy of the TPU3 is enhanced by the ability of a channel to affect the operation of one or more other channels without CPU intervention. Interchannel communication can be accomplished by issuing a link service request to another channel, by controlling another channel directly, or by accessing the parameter RAM of another channel.

### 19.3.4 Programmable Channel Service Priority

The TPU3 provides a programmable service priority level to each channel. Three priority levels are available. When more than one channel of a given priority requests service at the same time, arbitration is accomplished according to channel number. To prevent a single high-priority channel from permanently blocking other functions, other service requests of the same priority are performed in channel order after the lowest-numbered, highest-priority channel is serviced (i.e. round-robin).

### 19.3.5 Coherency

For data to be coherent, all available portions of the data must be identical in age, or must be logically related. As an example, consider a 32-bit counter value that is read and written as two 16-bit words. The 32-bit value is read-coherent only if both 16-bit portions are updated at the same time, and write-coherent only if both portions take effect at the same time. Parameter RAM hardware supports coherent access of two adjacent 16-bit parameters. The host CPU must use a long-word operation to guarantee coherency.

### 19.3.6 Emulation Support

Although factory-programmed time functions can perform a wide variety of control tasks, they may not be ideal for all applications. The TPU3 provides emulation capability that allows the development of new time functions. Emulation mode is entered by setting the EMU bit in TPUMCR. In emulation mode, an auxiliary bus connection is made between the DPTRAM and the TPU3, and access to DPTRAM via the intermodule bus is disabled. A 9-bit address bus, a 32-bit data bus, and control lines transfer information between the modules. To ensure exact emulation, DPTRAM module access timing remains consistent with access timing of the TPU microcode ROM control store.

To support changing TPU application requirements, Freescale has established a TPU function library. The function library is a collection of TPU functions written for easy assembly in combination with each other

or with custom functions. Refer to Freescale Programming Note, *Using the TPU Function Library and TPU Emulation Mode* (TPUPN00/D) for information about developing custom functions and accessing the TPU function library. Refer to *General TPU C Functions for the MPC500 Family* (AN2360/D) for more information about TPU functions in general and the *TPU Literature Package* (TPULITPAK/D) for more information about specific functions.

### 19.3.7 TPU3 Interrupts

Each of the TPU3 channels can generate an interrupt service request. Interrupts for each channel must be enabled by writing to the appropriate control bit in the channel interrupt enable register (CIER). The channel interrupt status register (CISR) contains one interrupt status flag per channel. Time functions set the flags. Setting a flag bit causes the TPU3 to make an interrupt service request if the corresponding channel interrupt enable bit is set.

The TPU3 can generate one of 32 possible interrupt request levels on the IMB3. The value driven onto  $\overline{\text{IRQ}}[7:0]$  represents the interrupt level programmed in the IRL field of the TPU interrupt configuration register (TICR). Under the control of the ILBS bits in the ICR, each interrupt request level is driven during one of four different time-multiplexed time slots, with eight levels communicated per time slot. No hardware priority is assigned to interrupts. Furthermore, if more than one source on a module requests an interrupt at the same level, the system software must assign a priority to each source requesting at that level. Figure 19-2 displays the interrupt level scheme.

Figure 19-2. TPU3 Interrupt Levels

### 19.3.8 Prescaler Control for TCR1

Timer count register 1 (TCR1) is clocked from the output of a prescaler. The following fields control TCR1:

- The PSCK and TCR1P fields in TPUMCR
- The DIV2 field in TPUMCR2
- The EPSCKE and EPSCK fields in TPUMCR3.

The rate at which TCR1 is incremented is determined as follows:

- The user selects either the standard prescaler (by clearing the enhanced prescaler enable bit, EPSCKE, in TPUMCR3) or the enhanced prescaler (by setting EPSCKE).
  - If the standard prescaler is selected (EPSCKE = 0), then the PSCK bit determines whether the standard prescaler divides the system clock input by 32 (PSCK = 0) or 4 (PSCK = 1)

- If the enhanced prescaler is selected (EPSCKE = 1), the EPSCK bits select a value by which the system clock is divided. The lowest frequency for TCR1 clock is system clock divided by 64x8. The highest frequency for TCR1 clock is system clock divided by two (2x1). See [Table 19-2](#) and [Table 19-3](#).

**Table 19-2. Enhanced TCR1 Prescaler Divide Values**

| EPSCK Value        | Divide System Clock By |
|--------------------|------------------------|
| 0x00               | 2                      |
| 0x01               | 4                      |
| 0x02               | 6                      |
| 0x03               | 8                      |
| 0x04, 0x05,...0x1d | 10,12,...60            |
| 0x1e               | 62                     |
| 0x1f               | 64                     |

- The output of either the standard prescaler or the enhanced prescaler is then divided by 1, 2, 4, or 8, depending on the value of the TCR1P field in the TPUMCR.

**Table 19-3. TCR1 Prescaler Values**

| TCR1P Value | Divide by |
|-------------|-----------|
| 0b00        | 1         |
| 0b01        | 2         |
| 0b10        | 4         |
| 0b11        | 8         |

- If the TPUMCR2[DIV2] bit is one, the TCR1 counter increments at a rate of the internal clock divided by two. If DIV2 is zero, the TCR1 increment rate is defined by the output of the TCR1 prescaler (which, in turn, takes as input the output of either the standard or enhanced prescaler).

[Figure 19-3](#) shows a diagram of the TCR1 prescaler control block.

Figure 19-3. TCR1 Prescaler Control

### 19.3.9 Prescaler Control for TCR2

Timer count register 2 (TCR2), like TCR1, is clocked from the output of a prescaler. The T2CG (TCR2 clock/gate control) bit and the T2CSL (TCR2 counter clock edge) bit in TPUMCR determine T2CR2 pin functions. Refer to [Table 19-4](#).

Table 19-4. TCR2 Counter Clock Source

| T2CSL | T2CG | TCR2 Clock                     |
|-------|------|--------------------------------|
| 0     | 0    | Rise transition T2CLK          |
| 0     | 1    | Gated system clock             |
| 1     | 0    | Fall transition T2CLK          |
| 1     | 1    | Rise and fall transition T2CLK |

The function of the T2CG bit is shown in [Figure 19-4](#).

When T2CG is set, the external T2CLK pin functions as a gate of the DIV8 clock (the TPU3 system clock divided by eight). In this case, when the external TCR2 pin is low, the DIV8 clock is blocked, preventing it from incrementing TCR2. When the external TCR2 pin is high, TCR2 is incremented at the frequency of the DIV8 clock. When T2CG is cleared, an external clock from the TCR2 pin, which has been synchronized and fed through a digital filter, increments TCR2. The duration between active edges on the T2CLK clock pin must be at least nine system clocks.

TPUMCR3[TCR2PSCK2] and TPUMCR[TCR2] determine how the clock source is divided to provide the output, see [Table 19-5](#). [Figure 19-4](#) illustrates the TCR2 pre-divider and pre-scaler control.

**Figure 19-4. TCR2 Prescaler Control**

Table 19-5 is a summary of prescaler output (assuming a divide-by-one value for the pre-divider prescaler).

**Table 19-5. TCR2 Prescaler Control**

| TCR2 Value | Internal Clock Divide Ratio |               | External Clock Divide Ratio |               |
|------------|-----------------------------|---------------|-----------------------------|---------------|
|            | TCR2PSCK2 = 0               | TCR2PSCK2 = 1 | TCR2PSCK2 = 0               | TCR2PSCK2 = 1 |
| 0b00       | 8                           | 8             | 1                           | 1             |
| 0b01       | 16                          | 24            | 2                           | 3             |
| 0b10       | 32                          | 56            | 4                           | 7             |
| 0b11       | 64                          | 120           | 8                           | 15            |

## 19.4 Programming Model

The TPU3 memory map contains three groups of registers:

- System configuration registers
- Channel control and status registers
- Development support and test verification registers

All registers except the channel interrupt status register (CISR) must be read or written by means of half-word (16-bit) or word (32-bit) accesses. The address space of the TPU3 memory map occupies 512 bytes. Unused registers within the 512-byte address space return zeros when read.

Table 19-6 shows the TPU3 address map.

**Table 19-6. TPU3 Register Map**

| Address                              | Register                                                                            |

**Figure 19-5. TPUMCR — TPU Module Configuration Register**

**Table 19-7. TPUMCR Bit Description**

| Bits | Name  | Description                                                                                                                                                                                                                                                                                                                                                                           |
|------|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | STOP  | Low-power stop mode enable. If the STOP bit in TPUMCR is set, the TPU3 shuts down its internal clocks, shutting down the internal microengine. TCR1 and TCR2 cease to increment and retain the last value before the stop condition was entered. The TPU3 asserts the stop flag (STF) in TPUMCR to indicate that it has stopped.<br>0 Enable TPU3 clocks<br>1 Disable TPU3 clocks     |
| 1:2  | TCR1P | Timer Count Register 1 prescaler control. TCR1 is clocked from the output of a prescaler. The prescaler divides its input by 1, 2, 4, or 8. This is a write-once field unless the PWOD bit in TPUMCR3 is set.<br>00 Divide by 1<br>01 Divide by 2<br>10 Divide by 4<br>11 Divide by 8<br>Refer to <a href="#">Section 19.3.8, “Prescaler Control for TCR1”</a> for more information.  |
| 3:4  | TCR2P | Timer Count Register 2 prescaler control. TCR2 is clocked from the output of a prescaler. The prescaler divides this input by 1, 2, 4, or 8. This is a write-once field unless the PWOD bit in TPUMCR3 is set.<br>00 Divide by 1<br>01 Divide by 2<br>10 Divide by 4<br>11 Divide by 8<br>Refer to <a href="#">Section 19.3.9, “Prescaler Control for TCR2”</a> for more information. |
| 5    | EMU   | Emulation control. In emulation mode, the TPU3 executes microinstructions from DPTRAM exclusively. Access to the DPTRAM via the IMB3 is blocked, and the DPTRAM is dedicated for use by the TPU3. After reset, this bit can be written only once.<br>0 TPU3 and DPTRAM operate normally<br>1 TPU3 and DPTRAM operate in emulation mode <sup>1</sup>                                   |
| 6    | T2CG  | TCR2 clock/gate control<br>0 TCR2 pin used as clock source for TCR2<br>1 TCR2 pin used as gate of DIV8 clock for TCR2<br>Refer to <a href="#">Section 19.3.9, “Prescaler Control for TCR2”</a> for more information.                                                                                                                                                                  |
| 7    | STF   | Stop flag.<br>0 TPU3 is operating normally<br>1 TPU3 is stopped (STOP bit has been set)                                                                                                                                                                                                                                                                                               |
| 8    | SUPV  | Supervisor data space<br>0 Assignable registers are accessible from user or supervisor privilege level<br>1 Assignable registers are accessible from supervisor privilege level only                                                                                                                                                                                                  |

**Table 19-7. TPUMCR Bit Description (continued)**

| Bits  | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|-------|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 9     | PSCK  | Standard prescaler clock. Note that this bit has no effect if the extended prescaler is selected (EPSCKE = 1).<br>0 $f_{SYS} \div 32$ is input to TCR1 prescaler, if standard prescaler is selected<br>1 $f_{SYS} \div 4$ is input to TCR1 prescaler, if standard prescaler is selected                                                                                                                                                                                                                                                     |
| 10    | TPU3  | TPU3 enable. The TPU3 enable bit provides compatibility with the TPU. If running TPU code on the TPU3, the microcode size should not be greater than 2 Kbytes and the TPU3 enable bit should be cleared to zero. The TPU3 enable bit is write-once after reset. The reset value is one, meaning that the TPU3 will operate in TPU3 mode.<br>0 TPU mode; zero is the TPU reset value<br>1 TPU3 mode; one is the TPU3 reset value<br>NOTE: The programmer should not change this value unless necessary when developing custom TPU microcode. |
| 11    | T2CSL | TCR2 counter clock edge. This bit and the T2CG control bit determine the clock source for TCR2. Refer to <a href="#">Section 19.3.9, “Prescaler Control for TCR2”</a> for details.                                                                                                                                                                                                                                                                                                                                                          |
| 12:15 | —     | Reserved. These bits are used for the IARB (interrupt arbitration ID) field in TPU3 implementations that use hardware interrupt arbitration.                                                                                                                                                                                                                                                                                                                                                                                                |

<sup>1</sup> If all TPUs connected to a DPTRAM are stopped, the DPTRAM is accessible.

## 19.4.2 Development Support Control Register (DSCR)

This register is accessible only when the TPU is in test mode; see [Section 19.4.14, “Factory Test Registers.”](#)

|        | MSB                                  |   |   |   |   |     |      |     |   |     |    |    |    |    | LSB |    |

**Figure 19-7. DSSR — Development Support Status Register**

**Table 19-9. DSSR Bit Descriptions**

| Bits  | Name | Description                                                                                                                                                                                                                                                                               |
|-------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:7   | —    | Reserved                                                                                                                                                                                                                                                                                  |
| 8     | BKPT | Breakpoint asserted flag. If an internal breakpoint caused the TPU3 to enter the halted state, the TPU3 asserts the BKPT signal on the IMB and sets the BKPT flag. BKPT remains set until the TPU3 recognizes a breakpoint acknowledge cycle, or until the IMB FREEZE signal is asserted. |
| 9     | PCBK | Microprogram Counter ( $\mu$ PC) breakpoint flag. PCBK is asserted if a breakpoint occurs because of a $\mu$ PC register match with the $\mu$ PC breakpoint register. PCBK is negated when the BKPT flag is cleared.                                                                      |
| 10    | CHBK | Channel register breakpoint flag. CHBK is asserted if a breakpoint occurs because of a CHAN register match with the CHAN register breakpoint register. CHBK is negated when the BKPT flag is cleared.                                                                                     |
| 11    | SRBK | Service request breakpoint flag. SRBK is asserted if a breakpoint occurs because of any of the service request latches being asserted along with their corresponding enable flag in the development support control register. SRBK is negated when the BKPT flag is cleared.              |
| 12    | TPUF | TPU3 FREEZE flag. TPUF is set whenever the TPU3 is in a halted state as a result of FREEZE being asserted. This flag is automatically negated when the TPU3 exits the halted state because of FREEZE being negated.                                                                       |
| 13:15 | —    | Reserved                                                                                                                                                                                                                                                                                  |

Table 19-10. TICR Bit Description

| Bits  | Name | Description                                                                                                                                                                                                                                                                                     |
|-------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:4   | —    | Reserved                                                                                                                                                                                                                                                                                        |
| 5:7   | CIRL | Channel interrupt request level. This three-bit field specifies the interrupt request level for all channels. This field is used in conjunction with the ILBS field to determine the request level of TPU3 interrupts.                                                                          |
| 8:9   | ILBS | Interrupt level byte select. This field and the CIRL field determine the level of TPU3 interrupt requests.<br>00 $\overline{\text{IRQ}}[0:7]$ selected<br>01 $\overline{\text{IRQ}}[8:15]$ selected<br>10 $\overline{\text{IRQ}}[16:23]$ selected<br>11 $\overline{\text{IRQ}}[24:31]$ selected |
| 10:15 | —    | Reserved. Note that bits 10:11 represent channel interrupt base vector (CIBV) bits in some TPU3 implementations.                                                                                                                                                                                |

### 19.4.5 Channel Interrupt Enable Register (CIER)

The channel interrupt enable register (CIER) allows the CPU to enable or disable the ability of individual TPU3 channels to request interrupt service. Setting the appropriate bit in the register enables a channel to make an interrupt service request; clearing a bit disables the interrupt.

Figure 19-9. CIER — Channel Interrupt Enable Register

Table 19-11. CIER Bit Descriptions

| Bits | Name     | Description                                                                                                                                                                      |

### 19.4.6 Channel Function Select Registers (CFSR<sub>n</sub>)

Encoded 4-bit fields within the channel function select registers specify one of 16 time functions to be executed on the corresponding channel. Encodings for predefined functions are found in [Table D-1](#) and [Table D-2](#).

**Figure 19-10. CFSR0 — Channel Function Select Register 0**

**Figure 19-11. CFSR1 — Channel Function Select Register 1**

| Name     | Description                                                                                                                                                                            |
|----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CH[15:0] | Encoded time function for each channel. Encoded four-bit fields in the channel function select registers specify one of 16 time functions to be executed on the corresponding channel. |

### 19.4.7 Host Sequence Registers (HSQR<sub>n</sub>)

The host sequence field selects the mode of operation for the time function selected on a given channel. The meaning of the host sequence bits depends on the time function specified. See [Appendix D, “TPU3 ROM Functions,”](#) for definitions of the host service request bits for the predefined TPU ROM functions.

## 19.4.8 Host Service Request Registers (HSRR $n$ )

The host service request field selects the type of host service request for the time function selected on a given channel. The meaning of the host service request bits is determined by time function microcode. See [Appendix D, “TPU3 ROM Functions,”](#) the *TPU Reference Manual* and the *Freescall TPU Literature Package* for more information.

|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CH[15:0] | <p>Encoded type of host service. The host service request field selects the type of host service request for the time function selected on a given channel. The meaning of the host service request bits depends on the time function specified.</p> <p>A host service request field cleared to 0b00 signals the host that service is completed by the microengine on that channel. The host can request service on a channel by writing the corresponding host service request field to one of three non-zero states. The CPU must monitor the host service request register until the TPU3 clears the service request to 0b00 before any parameters are changed or a new service request is issued to the channel.</p> |

### 19.4.9 Channel Priority Registers (CPR<sub>x</sub>)

The channel priority registers (CPR1, CPR2) assign one of three priority levels to a channel or disable the channel. See [Appendix D, “TPU3 ROM Functions,”](#) for more information.

| 01                    | Low      | 1 out of 7            |
| 10                    | Middle   | 2 out of 7            |
| 11                    | High     | 4 out of 7            |

### 19.4.10 Channel Interrupt Status Register (CISR)

The channel interrupt status register (CISR) contains one interrupt status flag per channel. Time functions specify via microcode when an interrupt flag is set. Setting a flag causes the TPU3 to make an interrupt service request if the corresponding CIER bit is set. To clear a status flag, read CISR, then write a zero to the appropriate bit.

#### NOTE

CISR is the only TPU3 register that can be accessed on a byte basis.

**Figure 19-21. TPUMCR2 — TPU Module Configuration Register 2**

**Table 19-18. TPUMCR2 Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:6  | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 7    | DIV2 | Divide by 2 control. When asserted, the DIV2 bit, along with the TCR1P bit and the PSCK bit in the TPUMCR, determines the rate of the TCR1 counter in the TPU3. If set, the TCR1 counter increments at a rate of two system clocks. If negated, TCR1 increments at the rate determined by control bits in the TCR1P and PSCK fields.<br>0 TCR1 increments at rate determined by control bits in the TCR1P and PSCK fields of the TPUMCR register<br>1 Causes TCR1 counter to increment at a rate of the system clock divided by two |

**Table 19-18. TPUMCR2 Bit Descriptions (continued)**

| Bits  | Name     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------|----------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 8     | SOFT RST | Soft reset. The TPU3 performs an internal reset when both the SOFT RST bit in the TPUMCR2 and the STOP bit in TPUMCR are set. The CPU must write zero to the SOFT RST bit to bring the TPU3 out of reset. The SOFT RST bit must be asserted for at least nine clocks.<br>0 Normal operation<br>1 Puts TPU3 in reset until bit is cleared<br>NOTE: Do not attempt to access any other TPU3 registers when this bit is asserted. When this bit is asserted, it is the only accessible bit in the register.   |
| 9:10  | ETBANK   | Entry table bank select. This field determines the bank where the microcoded entry table is situated. After reset, this field is 0b00. This control bit field is write once after reset. ETBANK is used when the microcode contains entry tables not located in the default bank 0. To execute the ROM functions on this MCU, ETBANK[1:0] must be 00. Refer to <a href="#">Table 19-19</a> .<br>NOTE: This field should not be modified by the programmer unless necessary because of custom microcode.    |
| 11:13 | FPSCK    | Filter prescaler clock. The filter prescaler clock control bit field determines the ratio between system clock frequency and minimum detectable pulses. The reset value of these bits is zero, defining the filter clock as four system clocks. Refer to <a href="#">Table 19-20</a> .                                                                                                                                                                                                                     |
| 14    | T2CF     | T2CLK pin filter control. When asserted, the T2CLK input pin is filtered with the same filter clock that is supplied to the channels. This control bit is write once after reset.<br>0 Uses fixed four-clock filter<br>1 T2CLK input pin filtered with same filter clock that is supplied to the channels                                                                                                                                                                                                  |
| 15    | DTPU     | Disable TPU3 pins. When the disable TPU3 control pin is asserted, pin TP15 is configured as an input disable pin. When the TP15 pin value is zero, all TPU3 output pins are three-stated, regardless of the pins function. The input is not synchronized. This control bit is write once after reset.<br>0 TP15 functions as normal TPU3 channel<br>1 TP15 pin configured as output disable pin. When TP15 pin is low, all TPU3 output pins are in a high-impedance state, regardless of the pin function. |

**Table 19-19. Entry Table Bank Location**

| ETBANK | Bank |
|--------|------|
| 00     | 0    |
| 01     | 1    |
| 10     | 2    |
| 11     | 3    |

**Table 19-20. System Clock Frequency/Minimum Guaranteed Detected Pulse**

| Filter Control | Divide By | 20 MHz      | 33 MHz       | 40 MHz       | 56 MHz       |
|----------------|-----------|-------------|--------------|--------------|--------------|
| 000            | 4         | 200 ns      | 121 ns       | 100 ns       | 71 ns        |

**Figure 19-22. TPUMCR3 — TPU Module Configuration Register 3**
**Table 19-21. TPUMCR3 Bit Descriptions**

| Bits  | Name      | Description                                                                                                                                                                                           |
|-------|-----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:6   | —         | Reserved                                                                                                                                                                                              |
| 7     | PWOD      | Prescaler write-once disable bit. The PWOD bit does not lock the EPSCK field and the EPSCKE bit.<br>0 Prescaler fields in MCR are write-once<br>1 Prescaler fields in MCR can be written anytime      |
| 8     | TCR2PSCK2 | TCR2 prescaler 2<br>0 Prescaler clock source is divided by one.<br>1 Prescaler clock is divided. See divider definitions in <a href="#">Table 19-5</a> .                                              |
| 9     | EPSCKE    | Enhanced pre-scaler enable<br>0 Disable enhanced prescaler (use standard prescaler)<br>1 Enable enhanced prescaler. System clock will be divided by the value in EPSCK field.                         |
| 10    | —         | Reserved                                                                                                                                                                                              |
| 11:15 | EPSCK     | Enhanced prescaler value that will be loaded into the enhanced prescaler counter. Prescaler value(EPSCK + 1) x 2. Refer to <a href="#">Section 19.3.8, “Prescaler Control for TCR1,”</a> for details. |

### 19.4.13 SIU Test Register (SIUTST)

Figure 19-23. SIUTST — SIU Test Register

Table 19-22. SIUTST Bit Descriptions

| Bits | Name    | Description                                                                                                                                                                           |
|------|---------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | TPU_DBG | This enables the test features of the TPU for use by TPU debuggers. It should only be enabled while debugging TPU microcode.<br>0 TPU debugging is disabled<br>1 TPU debug is enabled |
| 1:31 | —       | Reserved, always clear to 0.                                                                                                                                                          |

### 19.4.14 Factory Test Registers

Table 19-23 shows registers that are used for factory test only. The TPU Development Support registers are also used by TPU debuggers. They can only be used if the TPU is put into its test mode.

Table 19-23. Registers Used for Factory Test Only

| Name                                        | Address   |           |
|---------------------------------------------|-----------|-----------|
|                                             | TPU_A     | TPU_B     |
| Link Register (LR)                          | 0x30 4022 | 0x30 4422 |
| Service Grant Latch Register (SGLR)         | 0x30 4024 | 0x30 4424 |
| Decoded Channel Number Register (DCNR)      | 0x30 4026 | 0x30 4426 |
| Internal Scan Data Register (ISDR)          | 0x30 402C | 0x30 442C |
| Internal Scan Control Register (ISCR)       | 0x30 402E | 0x30 442E |
| TPU3 Test Configuration Register (TCR)      | 0x30 4002 | 0x30 4402 |
| Development Support Control Register (DSCR) | 0x30 4004 | 0x30 4404 |
| Development Support Status Register (DSSR)  | 0x30 4006 | 0x30 4406 |

## 19.4.15 TPU3 Parameter RAM

The channel parameter registers are organized as one hundred 16-bit words of RAM. Channels 0 to 15 have eight parameters. The parameter registers constitute a shared work space for communication between the CPU and the TPU3. The TPU3 can only access data in the parameter RAM. Refer to [Table 19-24](#).

**Table 19-24. Parameter RAM Address Offset Map**

| Channel<br>Number | Parameter    |              |              |              |              |              |              |              |
|-------------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|
|                   | 0            | 1            | 2            | 3            | 4            | 5            | 6            | 7            |
| 0                 | 0x30 4100(A) | 0x30 4102(A) | 0x30 4104(A) | 0x30 4106(A) | 0x30 4108(A) | 0x30 410A(A) | 0x30 410C(A) | 0x30 410E(A) |
|                   | 0x30 4500(B) | 0x30 4502(B) | 0x30 4504(B) | 0x30 4506(B) | 0x30 4508(B) | 0x30 450A(B) | 0x30 450C(B) | 0x30 450E(B) |
| 1                 | 0x30 4110(A) | 0x30 4112(A) | 0x30 4114(A) | 0x30 4116(A) | 0x30 4118(A) | 0x30 411A(A) | 0x30 411C(A) | 0x30 411E(A) |
|                   | 0x30 4510(B) | 0x30 4512(B) | 0x30 4514(B) | 0x30 4516(B) | 0x30 4518(B) | 0x30 451A(B) | 0x30 451C(B) | 0x30 451E(B) |

## 19.5 Time Functions

Descriptions of the MPC561/MPC563 pre-programmed time functions are shown in [Appendix D, “TPU3 ROM Functions.”](#)

## Chapter 20

# Dual-Port TPU3 RAM (DPTRAM)

The dual-port RAM (DPTRAM) module with TPU3 microcode storage support consists of a control register block and an 8-Kbyte array of static RAM, which can be used either as a microcode storage for TPU3 or as a general-purpose memory. The MPC561/MPC563 has one DPTRAM module. The module serves two TPU3 modules (A and B).

The DPTRAM module acts as a common memory on the IMB3 and allows the transfer of data to the two TPU3 modules. Therefore, the DPTRAM interface includes an IMB3 bus interface and two TPU3 interfaces. When the DPTRAM is being used in microcode mode, the array is only accessible to the TPU3 via a separate local bus, and not via the IMB3.

In the MPC561/MPC563, the DPTRAM base address register (RAMBAR) must be set to a particular value to fit into the IMB memory map of the part. The DPTRAM RAMBAR register *must* be programmed to 0xFFA0.

The DPTRAM module is powered by  $V_{DD}$  in normal operation. The entire array may be used as standby RAM if standby power is supplied via the IRAMSTBY pin of the MPC561/MPC563. IRAMSTBY must be supplied by an external source.

The DPTRAM may also be used as the microcode control store for up to two TPU3 modules when placed in a special emulation mode. In this mode the DPTRAM array may only be accessed by either or both of the TPU3 units simultaneously via separate emulation buses, and not via the IMB3.

The DPTRAM contains a multiple input signature calculator (MISC) in order to provide RAM data corruption checking. The MISC reads the DPTRAM address and generates a 32-bit data-dependent signature. This signature can then be checked by the host.

### NOTE

The RCPU cannot perform instruction fetches from any module on the IMB3 (including the DPTRAM). Only data accesses are permitted.

## 20.1 Features

- Eight Kbytes of static RAM
- Accessible by the CPU only if neither TPU3 is in emulation mode
- Low-power stop operation
  - Entered by setting the STOP bit in the DPTMCR
  - Does not enter low-power state while in TPU3 emulation mode for protection
- TPU3 microcode mode

- The DPTRAM array acts as a microcode storage for the TPU3 module. This provides a means of executing TPU3 code out of DPTRAM instead of TPU3 ROM.
- Includes built in check logic which scans the array contents and calculates the DPTRAM signature
- IMB3 bus interface
- Two TPU3 interface units
- Byte, half-word, or word accessible

## 20.2 DPTRAM Configuration Block Diagram

Figure 20-1. DPTRAM Configuration

## 20.3 Programming Model

The DPTRAM module consists of two separately addressable sections. The first is a set of memory-mapped control and status registers used for configuration (DPTMCR, RAMBAR, MISRH, MISRL, MISCNT) and testing (DPTTCR) of the DPTRAM array. The second section is the array itself.

All DPTRAM module control and status registers are located in supervisor data space. User read or write attempts will result in a bus error.

When the TPU3 is using the RAM array for microcode control storage, none of these control registers has any effect on the operation of the RAM array.

All addresses within the 64-byte control block will respond when accessed properly. Unimplemented addresses will return zeros for read accesses. Likewise, unimplemented bits within registers will return zero when read and will not be affected by write operations.

Table 20-1 shows the DPTRAM control and status registers. The addresses shown are offsets from the internal system base address (see Section 6.2.2.1.2, “Internal Memory Map Register (IMMR)”). Refer to Figure 1-3 to locate the DPTRAM control block in the MPC561/MPC563 address map.

**Table 20-1. DPTRAM Register Map**

| R/W Access              | Address   | Register                                                                                                                                                       | Reset Value            |

The DPTRAM array occupies an 8-Kbyte block. In the MPC561/MPC563, the array must be located at the address 0x30 2000. Refer to [Figure 1-3](#) and [Figure 20-2](#).

**Figure 20-2. DPTRAM Memory Map**

### 20.3.1 DPTRAM Module Configuration Register (DPTMCR)

This register defines the basic configuration of the DPTRAM module. The DPTMCR contains bits to configure the DPTRAM module for stop operation and for proper access privileges to the array. The register also contains the MISC control bits.

| 0    | STOP  | Low power stop (sleep) mode<br>0 DPTRAM clocks running<br>1 DPTRAM clocks shut down<br>Only the STOP bit in the DPTMCR may be accessed while the STOP bit is asserted. Accesses to other DPTRAM registers may result in unpredictable behavior. Note also that the STOP bit should be set and cleared independently of the other control bits in this register to guarantee proper operation. Changing the state of other bits while changing the state of the STOP bit may result in unpredictable behavior.<br>Refer to <a href="#">Section 20.4.4, “Stop Operation”</a> for more information. |
| 1:4  | —     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 5    | MISF  | Multiple input signature flag. MISF is readable at any time. This flag bit should be polled by the host to determine if the MISC has completed reading the DPTRAM. If MISF is set, the host should read the MISRH and MISRL registers to obtain the DPTRAM signature.<br>0 First signature not ready<br>1 MISC has read entire DPTRAM. Signature is latched in MISRH and MISRL and is ready to be read.                                                                                                                                                                                          |
| 6    | MISEN | Multiple input signature enable. MISEN is readable and writable at any time. The MISC will only operate when this bit is set and the MPC561/MPC563 is in TPU3 emulation mode. When enabled, the MISC will continuously cycle through the DPTRAM addresses, reading each and adding the contents to the MISR. In order to save power, the MISC can be disabled by clearing the MISEN bit.<br>0 MISC disabled<br>1 MISC enabled                                                                                                                                                                    |
| 7    | RASP  | RAM area supervisor/user program/data. The DPTRAM array may be placed in supervisor or unrestricted Space. When placed in supervisor space, (RASP = 1), only a supervisor may access the array. If a supervisor program is accessing the array, normal read/write operation will occur. If a user program is attempting to access the array, the access will be ignored and the address may be decoded externally.<br>0 Both supervisor and user access to DPTRAM allowed<br>1 Supervisor access only to DPTRAM allowed                                                                          |
| 8:15 | —     | Reserved. These bits are used for the IARB (interrupt arbitration ID) field in TPU3 implementations that use hardware interrupt arbitration.                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

### 20.3.2 DPTRAM Test Register (DPTTCR)

DPTTCR (test register, address 0x30 0002) is used only during factory testing of the MPC561/MPC563, and, if written, will generate a bus error.

### 20.3.3 RAM Base Address Register (RAMBAR)

The RAMBAR register is used to specify the 16 MSBs of the starting DPTRAM array location in the memory map. In order to be accessible in the MPC561/MPC563 memory map, this register *must* be programmed to 0xFFA0.

This register can be written only once after a reset. This prevents runaway software from inadvertently re-mapping the array. Since the locking mechanism is triggered by the first write after reset, the base

address of the array should be written in a single operation. Writing only one half of the register will prevent the other half from being written.

|-------|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:11  | A[8:19] | DPTRAM array base address. These bits specify the 11 high-order bits of the 24-bit base address of the DPTRAM array. This allows the array to be placed on a 8-Kbyte boundary anywhere in the memory map. Do not overlap the DPTRAM array memory map with other modules on the chip.<br>On the MPC561/MPC563 the value 0xFFA0 must be used for DPTRAM 6 Kbyte.                                                                                                                                |
| 12:14 | —       | Reserved. (Bit 12 represents A[20] in DPTRAM implementations that require it.)                                                                                                                                                                                                                                                                                                                                                                                                                |
| 15    | RAMDS   | RAM disabled. RAMDS is a read-only status bit. The DPTRAM array is disabled after a master reset because the RAMBAR register may be incorrect. When the array is disabled, it will not respond to any addresses on the IMB3. Access to the DPTRAM control register block is not affected when the array is disabled.<br>RAMDS is cleared by the DPTRAM module when a base address is written to the array address field of RAMBAR.<br>RAMDS = 0: DPTRAM enabled<br>RAMDS = 1: DPTRAM disabled |

### 20.3.4 MISR High (MISRH) and MISR Low Registers (MISRL)

The MISRH and MISRL together contain the 32-bit RAM signature calculated by the MISC. These registers are read-only and should be read by the host when the MISF bit in the MCR is set.

Exiting TPU3 emulation mode results in the reset of both MISRH and MISRL.

### 20.3.5 MISC Counter (MISCNT)

The MISCNT contains the address of the current MISC memory access. This register is read-only. Note that the naming of the A[31:0] bits represents little-endian bit encoding.

Exiting TPU3 emulation mode or clearing the MISEN bit in the DPTMCR results in the reset of this register.

|                            |                     |   |     |     |     |    |    |    |    |    |    |    |    |    |    |    |     |    |
|----------------------------|---------------------|---|-----|-----|-----|----|----|----|----|----|----|----|----|----|----|----|-----|----|

Figure 20-7. MISC Counter (MISCNT)

## 20.4 DPTRAM Operation

The DPTRAM module has several modes of operation. The following sections describe DPTRAM operation in each of these modes.

### 20.4.1 Normal Operation

In normal operation, read or write data accesses of 8-, 16-, or 32-bits are supported. Also, in normal operation, neither TPU3 accesses the array, nor do they have any effect on the operation of the DPTRAM module.

### 20.4.2 Standby Operation

The DPTRAM array uses a separate power supply IRAMSTBY to provide power to the DPTRAM array during a power-down phase.

In order to guarantee valid DPTRAM data during power-down, external low voltage inhibit circuitry (external to the MPC561/MPC563) must be designed to force the RESET pin of the MPC561/MPC563 into the active state before  $V_{DD}$  drops below its normal limit. This is necessary to inhibit spurious writes to the DPTRAM during power-down.

### 20.4.3 Reset Operation

When a synchronous reset occurs, a bus master is allowed to complete the current access. Thus a write bus cycle (byte, half word, or word) that is in progress when a synchronous reset occurs will be completed without error. Once a write already in progress has been completed, further writes to the DPTRAM array are inhibited.

If a reset is generated by an asynchronous reset such as the loss of clocks or software watchdog time-out, the contents of the DPTRAM array are not guaranteed. (Refer to [Chapter 7, “Reset”](#) for a description of MPC561/MPC563 reset sources, operation, control, and status.)

Reset will also reconfigure some of the fields and bits in the DPTRAM control registers to their default reset state. See the description of the control registers to determine the effect of reset on these registers.

### 20.4.4 Stop Operation

Setting DPTMCR[STOP] causes the module to enter its lowest power-consuming state. The DPTMCR can still be written to allow the STOP control bit to be cleared.

In stop mode, the DPTRAM array cannot be read or written. All data in the array is retained. The BIU continues operating to allow the CPU to access the STOP bit in the DPTMCR. The system clock remains stopped until the STOP bit is cleared or the DPTRAM module is reset.

The STOP bit is initialized to logical zero during reset. Only the STOP bit in the DPTMCR can be accessed while the STOP bit is asserted. Accesses to other DPTRAM registers may result in unpredictable behavior.

The DPTRAM will not enter stop mode if one of the TPUs is in emulation mode using DPTRAM (i.e., TPUMCR[EMU] = 1)

### 20.4.5 Freeze Operation

The FREEZE line on the IMB3 has no effect on the DPTRAM module. When the freeze line is set, the DPTRAM module will operate in its current mode of operation. If the DPTRAM module is not disabled, (RAMDS = 0), it may be accessed via the IMB3. If the DPTRAM array is being used by the TPU3 in emulation mode, the DPTRAM will still be able to be accessed by the TPU3 microengine.

### 20.4.6 TPU3 Emulation Mode Operation

To emulate TPU3 time functions, store in the RAM array the microinstructions required for all time functions. Storing microinstructions must be done with the DPTRAM in its normal operating mode and accessible from the IMB3. After the time functions are stored in the array, place one or both of the TPU3 units in emulation mode. The RAM array is then controlled by the TPU3 units and disconnected from the IMB3.

To use the DPTRAM for microcode accesses, set the EMU bit in the corresponding TPU3 module configuration register. Through the auxiliary buses, the TPU3 units can access word instructions simultaneously at a rate of up to 56 MHz.

When the DPTRAM array is being used by one or two of the TPU3 units, all accesses via the IMB3 are disabled. The control registers have no effect on the RAM array.

The contents of the RAM are validated using a multiple input signature calculator (MISC). MISC reads of the RAM are performed only when the MPC561/MPC563 is in emulation mode and the MISC is enabled (MISEN = 1 in the DPTMCR).

Refer to [Section 19.3.6, “Emulation Support”](#) for more information in TPU3 and DPTRAM operation in emulation mode.

## 20.5 Multiple Input Signature Calculator (MISC)

The integrity of the DPTRAM data is ensured through the use of a MISC. The DPTRAM data is read in reverse address order and a unique 32-bit signature is generated based on the output of these reads. MISC reads are performed when one of the TPU3 modules does not request back-to-back accesses to the DPTRAM provided that the MISEN bit in the DPTMCR is set.

The MISC generates the DPTRAM signature based on the following polynomial:

$$G(x) = 1 + x + x^2 + x^{22} + x^{31} \quad \text{Eqn. 20-1}$$

After the entire DPTRAM has been read and a signature has been calculated, the MISC sets the MISF bit in the DPTMCR. The host should poll this bit and enter a handling routine when the bit is found to be set.

The signature should then be read from the MISRH and MISRL registers and the host determines if it matches the predetermined signature.

The MISRH and MISRL registers are updated each time the MISC completes reading the entire DPTRAM regardless of whether or not the previous signature has been read or not. This ensures that the host reads the most recently generated signature.

The MISC can be disabled by clearing the MISEN bit in the DPTMCR.

### NOTE

The reset state of the DPTMCR[MISEN] is disabled.

## Chapter 21

### CDR3 Flash (UC3F) EEPROM

The MPC563 U-bus CDR3 (UC3F) EEPROM module is designed for use in embedded microcontroller (MCU) applications targeted for high-speed read performance and high-density byte count requirements.

The MPC563 has one Flash module of 512 Kbytes but the MPC561 has no internal Flash; this chapter, therefore, applies only to the MPC563. The UC3F array uses a single transistor Flash bit cell and is configured for a module of 512 Kbytes (524,288 bytes) of non-volatile memory (NVM). The UC3F module is divided into eight 64-Kbyte (65,536-byte) array blocks. Two blocks of the UC3F module memory map may be subdivided into two smaller blocks: a 48-Kbyte (49,152-byte) block and a 16-Kbyte (16,384-byte) block, or a 16-Kbyte block and a 48-Kbyte block.

The primary function of the UC3F EEPROM module is to serve as electrically programmable and erasable NVM to store program instructions and/or data. It is a class of non-volatile solid state silicon memory device consisting of an array of isolated elements, an electrical means for selectively adding and removing charge to the elements, and a means of selectively sensing the stored charge in the elements. When power is removed from the device, the stored charge of the isolated elements will be retained.

The UC3F EEPROM module is arranged into two major sections as shown in [Figure 21-1](#). The first section is the UC3F array used to store system program and data. The second section is the memory interface (MI) that controls operation of the UC3F array. The MI also serves as the interface between the UC3F array and a bus interface unit (BIU) which connects the UC3F array to the U-bus.

#### NOTE

If the Flash arrays are disabled in the IMMR register (FLEN=0), then neither the UC3F array or the UC3F control registers are accessible.

**Figure 21-1. Block Diagram for a 512 Kbyte UC3F Module Configuration**

The UC3F EEPROM module array is divided into array blocks to allow for independent erase, address attributes restrictions, and protection from program and erase for each array block. The size of a large array block in the UC3F module is fixed at 64 Kbytes. The size of a subdivided large block becomes the original large array block size minus 16 Kbytes (64 Kbytes – 16 Kbytes = 48 Kbytes). The size of the small block, which is the remainder of the large block, is always 16 Kbytes. The total UC3F EEPROM array is distributed into eight large blocks, two of which contain small blocks. Information is transferred to the UC3F EEPROM by long-word (64 bits), word (32 bits), half-word (16 bits), or byte (8 bits).

To improve system performance, each array read access retrieves 32 bytes of information. These 32 bytes may be copied into one of two read page buffers aligned to the low order addresses. The two read page buffers are independently updated by page management logic contained in the BIU which interfaces to the UC3F EEPROM module.

To prevent unnecessary page accesses from the array, the UC3F memory interface (MI) monitors the incoming address to determine if the required information is in one of the two read page buffers. This strategy allows the UC3F array to have an off page access and an on page access. In normal operation, write accesses to the UC3F array are not recognized except during program and erase operations.

The UC3F EEPROM uses an embedded hardware algorithm to program and erase the UC3F array. Special control logic is included to guard against accidental program or erase by requiring a specific series of read and write accesses to the UC3F control registers. External inputs provide a hardware protection mechanism to prevent accidental program and erase of UC3F array blocks. The hardware algorithm automatically performs all necessary applications of high voltage pulses and verify reads of the UC3F array to ensure that all bits are programmed and erased with sufficient margin to guarantee data integrity and reliability.

### 21.0.1 Features of the CDR3 Flash EEPROM (UC3F)

- High density single transistor Flash bit cell
- -40 to 125° C ambient temperature operating range
  - -40 to 85° C on the suffix C device
- 2.5-V to 2.7-V  $V_{DDF}$  operating range and 4.75-V to 5.25-V  $V_{FLASH}$  operating range
- Shadow information stored in special Flash NVM shadow locations
- 512 Kbytes using 64-Kbyte blocks
  - Two 16-Kbyte small blocks
- Array block restriction control for small and large blocks
  - Erase by array blocks
  - Array protection for program and erase operations
  - Array block assignment of supervisor or supervisor/user space
  - Array block assignment of data or instruction/data space
- Internal 64-bit data path architecture
- Page mode read
  - Retains two independent read page buffers
  - Read page size of 32 bytes (8 words).
- Word (32-bit) programming
- Embedded hardware program and erase algorithm
  - Uses internal oscillator to time program and erase pulses. Pulses are timed independently of system clock frequency
  - Automatically performs margin reads
- External Flash program or erase enable inputs for block 0 or entire Flash array (B0EPEE and EPEE)
- Low power disable via an external signal or UC3F register bit
- Censor mode for Flash memory array access restriction with a user bypass for unrestricted array access

## 21.1 UC3F Interface

The UC3F module contains a memory interface (MI) and an array core. The MI controls access of the array core and register block in the UC3F module.

The interface signals to the UC3F module consist of address inputs, data inputs, data outputs, a simple set of control signals for read and write operations, a set of register selects, and a set of register outputs which are used by the BIU. Three required supply pins power the module:  $V_{DDF}$ ,  $V_{SSF}$ , and  $V_{FLASH}$ .

The UC3F module is a fully asynchronous module and does not require a clock input for operation. All required clocks are generated internally using an internal oscillator, external test clock input, or internal delay circuits.

### 21.1.1 External Interface

The UC3F EEPROM module uses external pins to provide power supplies. These pins are listed in [Table 21-1](#).

**Table 21-1. UC3F External Interface Signals**

| Mnemonic    | I/O Type                       | Description             | Comments                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|-------------|--------------------------------|-------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $V_{DDF}$   | Power Pin                      | UC3F power supply       | To reduce noise in the read path no other circuits should be connected to the UC3F $V_{DDF}$ supply pin. This $V_{DD}$ pin must be isolated from all other $V_{DD}$ pins inside the device. The specified voltage range during operation is $2.6\text{ V} \pm 0.1\text{ V}$ .                                                                                                                                                                                                                                                                                     |
| $V_{SSF}$   | Ground Pin                     | UC3F ground             | To reduce noise in the read path no other circuits should be connected to the UC3F $V_{SSF}$ supply. This $V_{SS}$ pin must be isolated from all other $V_{SS}$ pins inside the device.                                                                                                                                                                                                                                                                                                                                                                           |
| $V_{FLASH}$ | Power Pin                      | UC3F 5-V power supply   | $V_{FLASH}$ provides a 5-V supply to the UC3F module which is used for read, program, and erase operations. $V_{FLASH}$ must be in the range of 4.75 V to 5.25 V ( $5\text{ V} \pm 5\%$ ) during operation.                                                                                                                                                                                                                                                                                                                                                       |
| EPEE        | External Program/Erase         | EPEE pin status         | The EPEE bit monitors the state of the external program/erase enable (EPEE) input. The UC3F module samples the EPEE input when EHV is asserted and holds that sampled state until EHV is negated.                                                                                                                                                                                                                                                                                                                                                                 |
| B0EPEE      | Block 0 External Program/Erase | Block 0 EPEE pin status | The B0EM bit monitors the state of Block 0 EPEE, B0EPEE, input. The UC3F module samples the B0EPEE input when EHV is asserted and holds that sampled value until EHV is negated. If B0EM = 1 when EHV is asserted, high voltage operations such as program or erase are enabled for either small block 0 or the lowest numbered block of the UC3F array regardless of the state of EPEE. If B0EM = 0 when EHV is asserted, high voltage operations are disabled for small block 0 or the lowest numbered block of the UC3F array regardless of the state of EPEE. |

## 21.2 Programming Model

The UC3F EEPROM module consists of a control register block, an addressable shadow row implemented in Flash, and an addressable main Flash memory array. The control registers are used to configure, program, erase and exercise the UC3F shadow row and Flash array.

### 21.2.1 UC3F EEPROM Control Registers

These supervisor-level control registers are used to control UC3F EEPROM module operation. On reset, the registers are loaded with default reset information. Several bits of the UC3F control registers are special Flash NVM registers which retain their state when power is removed from the UC3F EEPROM. These special NVM registers are identified in the individual register field and control bit descriptions.

#### 21.2.1.1 Register Addressing

The UC3F module control registers, shown in Table 21-2, are selected with individual register selects generated from the BIU. As such, each Flash module that is designed using the UC3F EEPROM module may uniquely define the addressing of the control register block.

**Table 21-2. UC3F Register Programming Model**

| Address   | Register                                 |
|-----------|------------------------------------------|
| 0x2F C800 | Module Configuration (UC3FMCR)           |
| 0x2F C804 | Extended Module Configuration (UC3FMCRE) |
| 0x2F C808 | High Voltage Control (UC3FCTL)           |
| 0x2F C80C | Reserved                                 |

#### 21.2.1.2 UC3F EEPROM Configuration Register (UC3FMCR)

The UC3F module configuration register is used to configure the operation and access restrictions of the UC3F array and shadow row.

|------|---------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | STOP                                  | <p>Array stop control. Writes to the STOP bit have no effect while in program or erase operation (SES = 1). The STOP bit is always readable whenever the registers are enabled.</p> <p>When STOP = 1, the reset state of STOP is 1 and the UC3F array is disabled; internal circuits are switched into a low power state. The STOP bit may be used to implement low power standby modes or power management schemes. The UC3FMCR remains readable and writable when STOP = 1 so that the STOP bit may be deasserted. Attempts to program or erase the array while STOP = 1 have no effect. SES cannot be set to 1 when STOP = 1.</p> <p>When STOP = 0, the reset state of STOP is 0 and the UC3F array is enabled for accesses. All registers that were disabled with STOP = 1 are now enabled. A STOP recovery time of 1 <math>\mu</math>s is required for biases in the UC3F array to reach their appropriate states to resume normal operation. Operations to the UC3F array should be delayed for at least 1 <math>\mu</math>s after clearing the STOP bit.</p> <p>0 = UC3F array is enabled<br/>1 = UC3F array is disabled (low-power mode)</p>                                                                                                                              |
| 1    | $\overline{\text{LOCK}}$ <sup>1</sup> | <p>Lock control. The default reset state of <math>\overline{\text{LOCK}}</math> is 1. This enables writing of all fields in the Flash registers.</p> <p>Once the <math>\overline{\text{LOCK}}</math> bit has been asserted (<math>\overline{\text{LOCK}}</math> = 0) in normal operating mode, the write-lock can only be disabled again by a reset. When the device is in background debug mode and CSC = 0, the <math>\overline{\text{LOCK}}</math> bit may be written from a 0 to a 1.</p> <p>When the <math>\overline{\text{LOCK}}</math> control bit is cleared to 0, the write-locked register bits: FIC, SUPV, SBSUPV[0:1], DATA, SBDATA, PROTECT, SBPROTECT, and SBEN[0:1] are locked. Writes to these bits while <math>\overline{\text{LOCK}}</math> = 0 will have no effect.</p> <p><math>\overline{\text{LOCK}}</math> can be written to 0 once after reset when UC3FCTL[CSC] = 0 to allow protection of the write-locked register bits after initialization.</p> <p style="text-align: center;"><b>WARNING:</b></p> <p style="text-align: center;">If the lock protection mechanism is enabled (<math>\overline{\text{LOCK}}</math> = 0) before PROTECT and SBPROTECT are cleared, the device must use background debug mode to program or erase the UC3F EEPROM.</p> |
| 2    | —                                     | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| 3    | FIC                                   | <p>Force information censorship. The default reset state of FIC is normal censorship operation (FIC = 0). The FIC bit is write protected by the <math>\overline{\text{LOCK}}</math> bit and the UC3FCTL[CSC] bit. Writes will have no effect if <math>\overline{\text{LOCK}}</math> = 0 or CSC = 1. Once FIC is set (FIC = 1), it cannot be cleared except by a reset. The FIC bit can be read whenever the registers are enabled.</p> <p>The FIC bit is a censorship emulation mode used to aid in the development of custom techniques for controlling the ACCESS bit without setting CENSOR[0:1] to the information censorship state. Using FIC to force information censorship allows testing of the hardware and software for setting ACCESS without setting CENSOR[0:1] = 11 and risk permanently setting the device into an unusable information censorship state.</p> <p>0 = normal uc3f censorship operation<br/>1 = forces the uc3f into information censorship mode</p>                                                                                                                                                                                                                                                                                                |
| 4    | SIE                                   | <p>Shadow information enable. The default reset state of SIE is 0. The SIE bit is write protected in program operation (SES = 1 and PE = 0). The SIE bit can be read whenever the registers are enabled.</p> <p>When SIE = 1, normal array accesses are disabled, and the two shadow information rows are enabled. Array accesses are directed to the shadow row while SIE = 1. When an array location is read in this mode, only the lower 6 address bits are used to select which 64 bytes of the 512-byte shadow row are read. The upper address bits are not used for shadow row decoding. The read page buffer address monitor is reset whenever SIE is modified making the next UC3F array access an off page access.</p> <p>0 = normal array access<br/>1 = disables normal array access and selects the shadow information rows</p>                                                                                                                                                                                                                                                                                                                                                                                                                                       |

**Table 21-3. UC3FMCR Bit Descriptions (continued)**

| Bits | Name   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|------|--------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 5    | ACCESS | <p>Enable uncensored access. A censored access to the UC3F EEPROM is any access where the device is in the censored mode.</p> <p>The default reset state is ACCESS is a 0 so that FIC and CENSOR[0:1] control the state of censorship to the UC3F EEPROM array. All accesses to the UC3F EEPROM array is allowed if ACCESS = 1.</p> <p>ACCESS can be read whenever the registers are enabled. ACCESS provides a method to bypass the UC3F EEPROM module censorship.</p> <p>0 Censored - UC3F array access allowed only if the censorship state is no censorship<br/>1 Allows all UC3F array access</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| 6:7  | CENSOR | <p>Censor accesses. The CENSOR[0:1] bits are implemented using non-volatile register bits or CAM cells. The reset state of CENSOR[0:1] is user defined by the contents stored in the NVM register bits.</p> <p>CENSOR is not writable but the NVM register's data can be set or cleared to the desired reset state. Reading CENSOR while setting or clearing with the high voltage applied (CSC = 1 and HVS = 1) will return 0's.</p> <p>00 cleared censorship, UC3F array access allowed only if device is in uncensored mode<br/>01 no censorship, all UC3F array accesses allowed<br/>10 no censorship, all UC3F array accesses allowed<br/>11 information censorship, UC3F array access allowed only if device is in uncensored mode</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 8:15 | SUPV   | <p>Supervisor space. The SUPV bits are used to assign supervisor space restrictions for each block of the UC3F array. The index for the SUPV bit field is used to determine block assignment. For example, SUPV[0] is used for the supervisor space assignment of array block 0, while SUPV[4] is used for array block 4 Supervisor space assignment.</p> <p>Array block M is mapped into supervisor address space when SUPV[M] = 1, and only supervisor accesses are allowed to array block M. If SUPV[M] = 0, then array block M is mapped into unrestricted address space which allows both supervisor and user accesses to array block M.</p> <p>The SUPV bits are not actually used in the UC3F EEPROM module but are used by the BIU to determine access restrictions to UC3F array on a blockwise basis. The block addresses are decoded in the BIU to determine which array block is selected, and the selected block's SUPV bit is compared with the address space attributes to determine validity of an array access.</p> <p>When the small block function is enabled, the enabled small block portion of an array block is not controlled by the SUPV bit corresponding to the array block containing that small block. This particular small block is controlled by the appropriate SBSUPV bit while the remainder of that array block is controlled by its SUPV bit.</p> <p>0 array block M is placed in unrestricted address space<br/>1 array block M is placed in supervisor address space</p> |

**Table 21-3. UC3FMCR Bit Descriptions (continued)**

| Bits  | Name    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-------|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 16:23 | DATA    | <p>Data space. The DATA bits are write protected by <math>\overline{\text{LOCK}}</math> and CSC. Writes to DATA have no effect if <math>\overline{\text{LOCK}} = 0</math> or <math>\text{CSC} = 1</math>. The DATA bits may be read whenever the registers are enabled. Each array block of the UC3F EEPROM may be mapped into data or data and instruction address space. When array block M is mapped into data address space (<math>\text{DATA}[\text{M}] = 1</math>), only data accesses will be allowed. When array block M is mapped into both Data and Instruction address space (<math>\text{DATA}[\text{M}] = 0</math>), both data and instruction accesses will be allowed.</p> <p>The DATA bits are not actually used in the UC3F EEPROM module but are used by the BIU to determine access restrictions to UC3F array on a blockwise basis. The block addresses are decoded in the BIU to determine which array block is selected, and the selected block's DATA bit is compared with the address space attributes to determine validity of an array access.</p> <p>When the small block function is enabled, the enabled small block portion of an array block is not controlled by the DATA bit corresponding to the array block containing that small block. This particular small block is controlled by the appropriate SBDATA bit while the remainder of that array block is controlled by its DATA bit.</p> <p>0 array block M is placed in both data and instruction address spaces<br/>1 array block M is placed in data address space</p> |
| 24:31 | PROTECT | <p>Block protect. Each array block of the UC3F EEPROM can be individually protected from program or erase operation. The contents of array block M are protected from program or erase by setting <math>\text{PROTECT}[\text{M}] = 1</math>. The UC3F will perform all program and erase interlocks and complete the program or erase sequence, but the program and erase voltages are not applied to locations within the protected array block(s), blocks whose corresponding PROTECT bit is set to 1. By setting <math>\text{PROTECT}[\text{M}] = 0</math>, array block M is enabled for program and erase operation, and its contents may be altered by programming or erasing.</p> <p>When the small block function is enabled, the enabled small block portion of an array block is not controlled by the PROTECT bit corresponding to the array block containing that small block. This particular small block is controlled by the appropriate SBPROTECT bit while the remainder of that array block is controlled by its PROTECT bit.</p> <p>0 array block M is unprotected<br/>1 array block M is protected</p>                                                                                                                                                                                                                                                                                                                                                                                                                                       |

<sup>1</sup> Note that the LOCK bit is in a different bit location on the MPC563 than in the MPC555. It was at bit 0 of CMFMCR.

### 21.2.1.3 UC3F EEPROM Extended Configuration Register (UC3FMCRE)

The UC3FMCRE is an extended module configuration register used for configuring the small block functions. In addition, 16 bits of the UC3FMCRE are used to provide a source for module identification.

**Table 21-4. UC3FMCRE Bit Descriptions**

| Bits | Name   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------|--------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:1  | SBEN   | <p>Small block enable. When SBEN[M]=0, the corresponding small block M behaves logically as if the small block is still part of the larger host block. In addition, the small block protect bit (SBPROTECT[M]), the small block supervisor bit (SBSUPV[M]), the small block data bit (SBDATA[M]), and the small block BLOCK bit (SBBLOCK[M]) corresponding to small block M have no effect. The corresponding small block is controlled by the same protect, supervisor, data, and block bits that control its host block.</p> <p>When SBEN[M] = 1, the corresponding small block M can be programmed and erased independently of its host block. The corresponding small block protect bit, the small block supervisor bit, the small block data bit, and the small block bit are enabled by SBEN.</p> <p>For example: when SBEN[0] = 0, Small Block 0 (16 Kbytes) and the residual block (48 Kbytes) contained in the host block of Small Block 0 are programmed and erased as if the two blocks are one large array block (64 Kbytes). When SBEN[0] = 1, small block 0 and the residual block contained in the host block of small block 0 behave as two separate blocks, i.e. small block 0 and the residual block in small block 0's host block can be programmed and erased independently of each other.</p> <p>0 small block M behaves as part of the host block<br/>1 small block M functions independent of host block</p> |
| 2:3  | SBSUPV | <p>Small block supervisor space. Each small array block of the UC3F EEPROM may be mapped into supervisor or unrestricted address space. When small array block M is mapped into supervisor address space, SBSUPV[M] = 1, only supervisor accesses are allowed. When small block M is mapped to unrestricted address space, SBSUPV[M] = 0, both supervisor and user accesses are allowed.</p> <p>If SBEN[M] = 0, the corresponding small block M is logically part of the host block and SBSUPV[M] has no effect. Instead, the corresponding SUPV[M] bit will be used to determine if the small block is mapped to Supervisor or Unrestricted address space.</p> <p>Like the SUPV[0:7] bits, the SBSUPV bits are not actually used in the UC3F EEPROM module but are used by the BIU to determine access restrictions to the UC3F array. Block addresses are decoded in the BIU to determine which small array block is selected, and the selected small block's SBSUPV bit is compared with the address space attributes to determine validity of an array access.</p> <p>0 small block M is placed in unrestricted address space<br/>1 small block M is placed in supervisor address space</p>                                                                                                                                                                                                                                     |

Table 21-4. UC3FMCRE Bit Descriptions (continued)

| Bits  | Name      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

Table 21-5. UC3FCTL Bit Descriptions

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | HVS  | High voltage status. The HVS bit is for status only, and writes to HVS have no effect. During a program or erase operation, HVS is set (HVS = 1) to indicate when high voltage operations are in progress. The HVS bit will negate itself when the program or erase operation completes successfully, EHV negates during program or erase to terminate the program/erase operation, HSUS is asserted to suspend the program/erase operation, resetting the module, or the internal hardware program/erase controller times out.<br>0 no program or erase of the UC3F array or shadow information or CENSOR bits in progress<br>1 program or erase of the UC3F array or shadow information or CENSOR bits in progress |

**Table 21-5. UC3FCTL Bit Descriptions (continued)**

| Bits  | Name    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-------|---------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1     | PEGOOD  | <p>Program/erase operation result. The PEGOOD bit is for status only. At the completion of a program or erase operation using the embedded hardware algorithm, the hardware algorithm will change the state of the PEGOOD bit to reflect whether or not the program or erase operation was successful.</p> <p>Note: PEGOOD will be set under the following conditions:</p> <ul style="list-style-type: none"> <li>• No failure occurred</li> <li>• No program or erase operation was requested (i.e., the Flash was protected)</li> </ul> <p>The PEGOOD bit is only valid after the hardware program/erase algorithm has cleared HVS. PEGOOD is reset when either EHV is asserted or SES is cleared. See <a href="#">Figure 21-5</a> for a timing diagram of when PEGOOD is valid.</p> <p>0 program or erase operation failed<br/>1 program or erase operation was successful</p>                                                                                |
| 2     | PEFI    | <p>Program/erase fail indicator. The PEFI bit is a status qualifier for the PEGOOD bit and is valid for the same times that PEGOOD is valid. In the event of an erase failure which returns PEGOOD = 0, the PEFI bit provides diagnostic information for the cause of the erase failure. If PEFI = 0, the erase failure occurred during the preprogramming step of the erase operation. If PEFI = 1, the erase failure occurred during the actual erase or APDE steps of the erase operation.</p> <p>In the event of a program failure which returns PEGOOD = 0, the PEFI bit indicates a program failure by reading as a 0. The PEFI bit should never return a 1 for a program failure.</p> <p>NOTE: The PEFI bit is meaningful only while PEGOOD is valid and PEGOOD = 0. PEFI is valid after HVS negates and prior to the assertion of EHV or negation of SES.</p> <p>0 Program operation failed if PEGOOD = 0<br/>1 Erase operation failed if PEGOOD = 0</p> |
| 3     | EPEE    | <p>EPEE pin status. The EPEE bit monitors the state of the external program/erase enable (EPEE) input. The UC3F module samples the EPEE input when EHV is asserted and holds that sampled state until EHV is negated.</p> <p>0 high voltage operations are not possible<br/>1 high voltage operations are possible</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 4     | B0EM    | <p>Block 0 EPEE pin status. The B0EM bit monitors the state of the Block 0 EPEE, B0EPEE, input. The UC3F module samples the B0EPEE input when EHV is asserted and holds that sampled value until EHV is negated.</p> <p>If B0EM = 1 when EHV is asserted, high voltage operations such as program or erase are enabled for either small block 0 or the lowest numbered block of the UC3F array regardless of the state of EPEE.</p> <p>If B0EM = 0 when EHV is asserted, high voltage operations are disabled for small block 0 or the lowest numbered block of the UC3F array regardless of the state of EPEE.</p> <p>0 High voltage operations are not possible for block 0 or lowest numbered block<br/>1 High voltage operations are possible for block 0 or lowest numbered block.</p>                                                                                                                                                                      |
| 5:13  | —       | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 14:15 | SBBLOCK | <p>Small block program and erase select. The SBBLOCK bits are write-protected by the SES bit. SBBLOCK selects the UC3F EEPROM small array blocks for program and erase operation. When programming, only those blocks intended to be enabled for programming should have their corresponding BLOCK[M] or SBBLOCK[M] bit set.</p> <p>0 Small block M is not selected for program or erase<br/>1 Small Block M is selected for program or erase</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

Table 21-5. UC3FCTL Bit Descriptions (continued)

| Bits  | Name  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-------|-------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 16:23 | BLOCK | <p>Block program and erase select. The BLOCK bits are write protected by the SES bit. BLOCK selects the UC3F EEPROM array blocks for program and erase operation. All the blocks may be selected for program or erase operation at once.</p> <p>The UC3F EEPROM configuration along with BLOCK determine which array blocks that may be programmed. The UC3F EEPROM array blocks that are enabled to be programmed by the program operation are the blocks whose corresponding BLOCK bit is set to 1. For example, if array blocks 2 and 5 are enabled for programming, BLOCK[2] and BLOCK[5] must be set to 1 while BLOCK[0], BLOCK[1], BLOCK[3], BLOCK[4], BLOCK[6], and BLOCK[7] are set to 0.</p> <p>The UC3F EEPROM configuration along with BLOCK determine the blocks that will be erased simultaneously. All array blocks whose corresponding BLOCK bits are set will be erased during the erase operation. For example, if BLOCK = 00100111, then array blocks 2, 5, 6, and 7 get erased when an erase operation is performed.</p> <p>0 Array block M is not selected for program or erase<br/>1 Array block M is selected for program or erase</p> |

| 28    | HSUS  | <p>Program/erase suspend. Setting the HSUS bit during an embedded hardware algorithm program or erase operation will force the UC3F EEPROM to suspend the current program or erase. The UC3F EEPROM will maintain all information necessary to resume the suspended operation.</p> <p>Array reads are possible while HSUS = 1. However, array reads must be done to locations that are not being affected by the program/erase operation that is currently being suspended. The UC3F EEPROM will NOT prevent read accesses to those locations. Reads to those locations will result in UNKNOWN data. Writes to the HSUS bit only have effect while EHV = 1. The HSUS bit is write locked by EHV = 0.</p> <p>0 Hardware program/erase behaves normally<br/>1 Any current hardware program/erase is suspended</p>                                                                                                                                                                                                                                                                                                                                              |
| 29    | PE    | <p>Program or erase select. The PE bit is write protected by the SES bit. PE configures the UC3F EEPROM for programming or erasing. When PE = 0, the array is configured for programming and if SES = 1 the SIE bit will be write locked. When PE = 1, the array is configured for erasing and SES will not write lock the SIE bit.</p> <p>0 Configure for program operation<br/>1 Configure for erase operation</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |

**Table 21-5. UC3FCTL Bit Descriptions (continued)**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|------|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 30   | SES  | <p>Start-end program or erase sequence. The SES bit is write protected by the STOP, HVS, and EHV bits. The SES bit is used to signal the start and end of a program or erase sequence. At the start of a program or erase sequence, SES is set. This will lock STOP, PROTECT, SBPROTECT, BLOCK, SBBLOCK, SBEN, CSC, and PE. If PE = 0 and SES = 1, SIE will be write locked. At this point, the UC3F EEPROM is ready to receive either the programming writes or the erase interlock write.</p> <p>NOTE: The erase interlock write is a write to any UC3F EEPROM array location after SES is set and PE = 1.</p> <p>If PE = 0 and SES = 1, writes to the UC3F array are programming writes. The first programming write sets the address of the location to be programmed, and the data written is captured into the program data latch for programming into the UC3F array. All programming writes after the first programming write update the program data latch but do not change the address to be programmed.</p> <p>At the end of the program or erase operation, the SES bit must be cleared to return to normal operation and release the STOP, PROTECT, SBPROTECT, BLOCK, SBBLOCK, CSC, SBEN, and PE bits.</p> <p>0 UC3F EEPROM not configured for program or erase operation<br/>1 Configure UC3F EEPROM for program or erase operation</p> |
| 31   | EHV  | <p>Enable high voltage. EHV can be asserted only after the SES bit has been asserted and a valid programming write(s) or erase hardware interlock write has occurred. If an attempt is made to assert EHV when SES is negated, or if a valid programming write or erase hardware interlock write has not occurred since SES was asserted, EHV will remain negated.</p> <p>The external program or erase enable pin (EPEE) and EHV are used to control the application of the program or erase voltage to the UC3F EEPROM module. High voltage operations to the UC3F EEPROM array, special shadow locations or FLASH NVM registers can occur only if EHV = 1 and EPEE = 1.</p> <p>Only after the correct hardware and software interlocks have been applied to the UC3F EEPROM can EHV be set. Once EHV is set, SES cannot be changed and attempts to read the array will not be acknowledged.</p> <p>Clearing EHV during a program or erase operation will safely terminate the high voltage operation. If EHV is cleared while using the embedded hardware program/erase algorithm, the program/erase routine will abort the operation and exit normally.</p> <p>0 Program or erase pulse disabled<br/>1 Program or erase pulse enabled</p>                                                                                                          |

**Figure 21-5. PEGOOD Valid Time**

### 21.2.2 UC3F EEPROM Array Addressing

The UC3F array is divided into eight blocks, 64 Kbytes in size, which may be independently erased. Two blocks are host to a 16-Kbyte small block.

Seventeen bits of address are used to decode locations in the UC3F array. The read control logic in the UC3F EEPROM module decodes the upper 14 bits of that address to determine if the desired data is currently stored in one of the two read page buffers. If the data is already present in one of the two read page buffers, a read operation is not completed to the UC3F array core, and 64 bits of data are transferred from the appropriate read page buffer to the BIU. This type of array read access is an on-page read.

In the event that the read control logic determines that the desired data is not contained within one of the read page buffers, a read access to the UC3F array core is completed and 32 bytes of data are transferred from the array core. Only the addressed 64 bits of data will be transferred to the BIU. This type of array read access is an off-page read. The BIU contains logic to implement the read page buffer update and replacement scheme to transfer the 32 bytes of data into the appropriate read page buffer. If the read page update and replacement scheme contains a random access mode that does not update the read page buffers, the 32 bytes of data retrieved from the UC3F array core will not be transferred into either read page buffer. The BIU is expected to contain page update logic for controlling the updating of the read page buffers.

Write accesses to the UC3F array have no effect except during program and erase operation.

### 21.2.3 UC3F EEPROM Shadow Row

The UC3F EEPROM module contains a special shadow row that is used to hold reset configuration data and user data. See [Figure 21-6](#).

The shadow row is accessed by setting UC3FMCR[SIE] = 1 and performing normal array accesses. Upon transitioning SIE (a 1-to-0 or 0-to-1 transition), the read page match decode circuit is reset so that the next array access is an off-page access.

The shadow row contains 512 bytes which are addressed for read accesses using the low order row and read page addresses.

The shadow row is implemented in the lowest numbered block of the array. In the case of a UC3F array configuration which also has a small block in the lowest numbered block of the array, the shadow row is contained in the small block. If SBEN[0] = 1 in this array configuration, the shadow row is treated as part of small block 0. SBPROTECT[0] and SBBLOCK[0] are used to control program and erase operation of the shadow row. If SBEN[0] = 0 in this array configuration, the shadow row is treated as part of the host block. The corresponding PROTECT and BLOCK bits are used to control program and erase operation of the shadow row.

#### NOTE

A module cannot read its own shadow row. On the MPC563 the program accessing the Flash shadow row must be executing from external memory or from internal SRAM.

Figure 21-6. Shadow Information

### 21.2.3.1 Reset Configuration Word (UC3FCFIG)

The UC3F EEPROM reset configuration word is implemented in the first word (ADDR[23:29] = 0x00) of the special shadow locations. The reset configuration word along with the rest of the shadow information words is located in supervisor data address space. The purpose of the reset configuration word is to provide the system with an alternative internal source for the reset configuration.

Note that with the exception of bit 20, the bits in the UC3FCFIG are identical to those in the USIU hard reset configuration word.

The reset state of UC3FCFIG is user programmable.

Table 21-6. RCW Bit Descriptions

| Bits  | Name      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|-------|-----------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0     | EARB      | External arbitration — Refer to <a href="#">Section 9.5.7, “Arbitration Phase”</a> for a detailed description of Bus arbitration. The default value is that internal arbitration hardware is used.<br>0 Internal arbitration is performed<br>1 External arbitration is assumed                                                                                                                                                                                                                                                                                                                                                                       |
| 1     | IP        | Initial interrupt prefix — This bit defines the initial value of the MSR[IP] immediately after reset. The MSR[IP] bit defines the Interrupt Table location.<br>0 MSR[IP] = 0 after reset<br>1 MSR[IP] = 1 after reset<br>The default value is 0. See <a href="#">Table 3-11</a> for more information.                                                                                                                                                                                                                                                                                                                                                |
| 2     | BDRV      | Bus pins drive strength — This bit determines the bus pins' (address, data, and control) driving capability to be either full or reduced drive. The bus default drive strength is full; upon default, it also causes the CLKOUT drive strength to be full. See <a href="#">Table 6-7</a> for more information. BDRV controls the default state of COM[1] in the SIUMCR.<br>0 Full drive<br>1 Reduced drive                                                                                                                                                                                                                                           |
| 3     | BDIS      | Boot disable — If the BDIS bit is set, then memory controller is not activated after reset. If it is cleared then the memory controller bank 0 is active immediately after reset such that it matches any addresses. If a write to the OR0 register occurs after reset this bit definition is ignored. The default value is that the memory controller is enabled to control the boot with the CS0 pin. See <a href="#">Section 10.7, “Global (Boot) Chip-Select Operation”</a> for more information.<br>0 Memory controller bank 0 is active and matches all addresses immediately after reset<br>1 Memory controller is not activated after reset. |
| 4:5   | BPS       | Boot port size — This field defines the port size of the boot device on reset (BR0[PS]). If a write to the OR0 register occurs after reset this field definition is ignored. See <a href="#">Table 10-5</a> and <a href="#">Table 10-8</a> for more information.<br>00 32-bit port (default)<br>01 8-bit port<br>10 16-bit port<br>11 Reserved                                                                                                                                                                                                                                                                                                       |
| 6:8   | —         | Reserved. These bits must not be high in the reset configuration word.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 9:10  | DBGC[0:1] | Debug pins configuration — See <a href="#">Section 6.2.2.1.1, “SIU Module Configuration Register (SIUMCR)”</a> for this field definition. The default value is that these pins function as: VFLS[0:1], $\overline{BI}$ , $\overline{BR}$ , $\overline{BG}$ and $\overline{BB}$ . See <a href="#">Table 6-8</a> .                                                                                                                                                                                                                                                                                                                                     |
| 11    | —         | Reserved.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 12    | ATWC      | Address type write enable configuration — The default value is that these pins function as $\overline{WE}$ pins.<br>0 $\overline{WE}[0:3]/\overline{BE}[0:3]/AT[0:3]$ functions as $\overline{WE}[0:3]/\overline{BE}[0:3]$<br>1 $\overline{WE}[0:3]/\overline{BE}[0:3]/AT[0:3]$ functions as AT[0:3]<br>See <a href="#">Table 6-7</a> .                                                                                                                                                                                                                                                                                                              |
| 13:14 | EBDF      | External bus division factor — This field defines the initial value of the external bus frequency. The default value is that CLKOUT frequency is equal to that of the internal clock (no division). See <a href="#">Table 8-9</a> .                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 15    | IWS       | Interlock write select — This bit determines which interlock write operation should be used during the clear censorship operation.<br>IWS always comes from the UC3FCFIG, it will never use the external reset configuration word (RSTCONF=0) or the default internal reset configuration word (RSTCONF=1 and $\overline{HC}$ =1).<br>0 Interlock write is a write to any UC3F array location<br>1 Interlock write is a write to the UC3FMCR register.                                                                                                                                                                                               |

Table 21-6. RCW Bit Descriptions (continued)

| Bits  | Name                  | Description                                                                                                                                                                                                                                                                                                                |
|-------|-----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 16    | PRPM                  | Peripheral mode enable — This bit determines if the chip is in peripheral mode. A detailed description is in <a href="#">Table 6-13</a> . The default value is no peripheral mode enabled.                                                                                                                                 |
| 17:18 | SC                    | Single chip select — This field defines the mode of the MPC563.<br>00 Extended chip, 32 bits data<br>01 Extended chip, 16 bits data<br>10 Single chip and show cycles (address)<br>11 Single chip<br>See <a href="#">Table 6-10</a> .                                                                                      |
| 19    | ETRE                  | Exception table relocation enable — This field defines whether the Exception Table Relocation feature in the BBC is enabled or disabled. The default state for this field is disabled. For more details, see <a href="#">Table 4-4</a> .                                                                                   |
| 20    | $\overline{HC}$       | Has configuration — This bit determines if the Flash Reset Configuration word is valid.<br>0 The Flash shadow row contains a valid Reset Configuration Word<br>1 The Flash shadow row does not contain a valid Reset Configuration Word                                                                                    |
| 21    | EN_COMP <sup>1</sup>  | Enable compression — This bit enables the operation of the MPC564 with compressed code. See <a href="#">Table 4-4</a> .                                                                                                                                                                                                    |
| 22    | EXC_COMP <sub>1</sub> | Exception compression — This bit determines the operation of the MPC564 with exceptions.<br>0 indicates the exceptions are all non-compressed. See <a href="#">Table 4-4</a> .<br>1 the MPC564 assumes that ALL the exception routines are in compressed code.                                                             |
| 23    | —                     | Reserved. | 26:27 | —                     | Reserved                                                                                                                                                                                                                                                                                                                   |
| 28:30 | ISB                   | Internal space base select — This field defines the initial value of the ISB field in the IMMR register. A detailed description is in <a href="#">Table 6-12</a> . The default state is that the internal memory map is mapped to start at address 0x0000_0000. This bit must not be high in the reset configuration word. |
| 31    | DME                   | Dual mapping enable — This bit determines whether Dual mapping of the internal Flash is enabled. For a detailed description refer to <a href="#">Table 10-11</a> . The default state is that dual mapping is disabled.<br>0 Dual mapping disabled<br>1 Dual mapping enabled                                                |

<sup>1</sup> This bit is available only on the MPC564.

During reset, the has configuration bit ( $\overline{HC}$ ) and the USIU configure the UC3F EEPROM module to provide UC3FCFIG. If  $\overline{HC} = 0$  and the USIU requests internal configuration during reset the reset configuration word will be provided by UC3FCFIG.

The default reset state of the UC3FCFIG after an erase operation of the UC3F module is no configuration word available ( $\overline{HC} = 1$ ).

## 21.2.4 UC3F EEPROM 512-Kbyte Array Configuration

Figure 21-8, the array configuration diagram, shows the UC3F configuration for the MPC563 512-Kbyte arrays.

Note: The shading indicates the shadow row.

**Figure 21-8. 512-Kbyte Array Configuration**

## 21.3 UC3F Operation

The following sections describe the operation of the UC3F EEPROM during various operational modes. The primary function of the UC3F EEPROM module is to serve as electrically erasable and programmable non-volatile memory for embedded application in microcontrollers.

### 21.3.1 Reset

The device signals a reset to the UC3F EEPROM by asserting the reset signal. A reset is the highest priority operation for the UC3F EEPROM and terminates all other operations. The UC3F EEPROM module uses reset to initialize register bits to their default reset value. If the UC3F EEPROM is in program or erase operation ( $UC3FCTL[EHV] = 1$  and  $UC3FCTL[SES] = 1$ ) and a reset is issued, the module will perform the needed interlocks to disable the high voltage without damage to the high voltage circuits. Reset terminates any other mode of operation and forces the UC3F EEPROM module to a state ready to receive accesses.

During power up and power down periods, it is assumed that the reset signal is asserted to prevent accidental program/erase disturb of the UC3F array.

## 21.3.2 Register Read and Write Operation

The UC3F EEPROM control registers are accessible for read or write operation at all times while the device is powered up and enabled except during reset.

## 21.3.3 Array Read Operation

The UC3F EEPROM array is available for a read operation under most conditions while the device is powered up. Reads of the array are not allowed in the following instances:

- During reset—When in information or cleared censorship with ACCESS = 0
- While the UC3F EEPROM is disabled—See [Section 21.3.10, “Disabled,”](#) for more information on disabling the UC3F EEPROM
- While the UC3F EEPROM is in STOP mode—See [Section 21.3.9, “Stop Operation,”](#) for more information on STOP mode
- While high voltage is applied to the array during program and erase operation —HVS = 1 or EHV = 1 and not suspended

The address of an incoming read access is compared to the address for which data is currently held in the read page buffers. If the data corresponding to the read address is currently held in one of the two read page buffers, the data is fetched from the appropriate read page buffer. A data fetch from a read page buffer is an on-page read operation [Section 21.3.3.1, “Array On-Page Read Operation.”](#) If the data is not contained in one of the read page buffers, 32 bytes of information is fetched from the UC3F array, and the addressed data is driven onto the data bus. A data fetch from the UC3F array is an off-page read operation.

### NOTE

After setting/clearing UC3FCTL[HSUS], reset, programming writes, erase interlock write, setting EHV, clearing SES or setting/clearing SIE, the page buffers may not contain valid information. The UC3F forces an off-page read before an on-page read can be accomplished to ensure data coherency.

For information regarding how the two read page buffers in the UC3F EEPROM are associated to array blocks, refer to [Section 21.2.2, “UC3F EEPROM Array Addressing.”](#)

The UC3F module is configured as a page mode memory. The UC3F module uses an internal address comparator to monitor incoming addresses to determine if the addressed information is stored in a read page buffer. When the address comparator determines that the requested information is not stored in a read page buffer, an array off-page read operation retrieves 32 bytes of data from the Flash array and transfers the addressed data to the data bus.

In the MPC563, the UC3F module contains two 32-byte read page buffers. In the module, one buffer is dedicated to the most recently accessed instruction fetches and the other read page buffer is dedicated to the most recently loaded data access.

### 21.3.3.1 Array On-Page Read Operation

An internal address comparator is used to determine if addressed information is stored in a read page buffer. If the address of a read access matches data contained in a read page buffer, that addressed data is transferred from the read page buffer to the data bus. An off-page read access to transfer data from the Flash array to the data bus is not performed in this case.

### 21.3.4 Shadow Row Select Read Operation

The normal array is accessed when the SIE register bit in the UC3FMCR = 0. When SIE = 1, reads to the array access the shadow information row.

### 21.3.5 Array Program/Erase Interlock Write Operation

The only valid writes to the UC3F array are program or erase interlock writes. In the case of program interlock writes, the address of the write determines the location to be programmed while the data written is transferred to the program data latches to be programmed into the array. Address and data written during an erase interlock write is a “don’t care” and is not stored anywhere.

### 21.3.6 High Voltage Operations

There are two fundamental high voltage operations, program and erase. Program changes a UC3F array bitcell from a logic 1 state to a logic 0 state and is a selective operation performed on up to 32 bits at a time. Erase changes a UC3F array bitcell from a logic 0 state to a logic 1 state and is a bulk operation performed on one block or multiple blocks of the UC3F array.

#### 21.3.6.1 Overview of Program/Erase Operation

The embedded hardware program/erase algorithm relies on an internal state machine to perform the program and erase sequences. The embedded hardware algorithm uses an internal oscillator to control the high voltage pulse duration and hardware control logic. The embedded hardware algorithm is also responsible for performing all margin reads and applying high voltage pulses to ensure each bit is programmed or erased with sufficient margin. Upon successful program or erase operation, the program/erase hardware control logic terminates the program or erase operation with a pass status (PEGOOD = 1). The program/erase control logic will time out in the event that the maximum program or erase time is exceeded and return a fail status (PEGOOD = 0).

### 21.3.7 Programming

To modify the charge stored in an isolated element of the UC3F bit from a logic 1 state to a logic 0 state, a programming operation is required. This programming operation applies the required voltages to change the charge state of the selected bits without changing the logic state of any other bits in the UC3F array. The program operation cannot change the logic 0 state to a logic 1 state; this transition must be done by the erase operation. Programming uses a program data latch to store the data to be programmed and an address latch to store the word address to be programmed. The UC3F Array may be programmed by byte (8 bits), half-word (16 bits), or word (32 bits).

Blocks of the UC3F EEPROM that are protected ( $\text{PROTECT}[M] = 1$ ,  $\text{SBEN}[N] = 1$  and  $\text{SBPROTECT}[N] = 1$ ) will not be programmed. Also, if  $\text{EPEE} = 0$ , no programming voltages will be applied to the array. If  $\text{B0EPEE} = 0$ , no programming voltages will be applied to block 0 or small block 0 depending on the state of  $\text{SBEN}[0]$  and the configuration of the array.

### 21.3.7.1 Program Sequence

The UC3F EEPROM module requires a sequence of writes to the high voltage control register (UC3FCTL) and to the program data latch in order to enable the high voltage to the array or shadow information for program operation. The required hardware program sequence follows.

1. Write  $\text{PROTECT}[0:7]$  and  $\text{SBPROTECT}[0:1]$  to disable protection on blocks to be programmed.
2. Write  $\text{BLOCK}[0:7]$  and  $\text{SBBLOCK}[0:1]$  to select the array blocks to be programmed,  $\text{SES} = 1$  and  $\text{PE} = 0$  in the UC3FCTL register.

#### NOTE

$\text{BLOCK}[0:7]$  and  $\text{SBBLOCK}[0:1]$  in conjunction with  $\text{SBEN}[0:1]$  determine which blocks/small blocks in the array are enabled for programming operation. Just because a  $\text{BLOCK}$  or  $\text{SBBLOCK}$  bit is enabled (set to 1), no programming can occur in the corresponding block/small block unless the programming operation specifically targets an address location within that block/small block to program. If  $\text{BLOCK}$  or  $\text{SBBLOCK}$  is not set to 1, no address locations in that corresponding block or small block can be programmed.

3. Programming write — A successful write to the array location to be programmed. This write updates the program data latch with the information to be programmed. In addition, the address of the first programming write is latched in the UC3F memory interface block. All accesses of the array after the first write are to the same address regardless of the address provided. Thus the locations accessed after the first programming write are limited to the location to be programmed. The last write to the program data latch is saved for programming.

#### NOTE

If a byte of the program data latch has not received a programming write, no programming voltages will be applied to the corresponding byte in the array. Once  $\text{EHV}$  has been set, writes to the program data latch are disabled until  $\text{EHV}$  is cleared to 0.

4. Write  $\text{EHV} = 1$  in the UC3FCTL register.

#### NOTE

The values of the  $\text{EPEE}$  and  $\text{B0EPEE}$  inputs are latched with the assertion of  $\text{EHV}$  to determine the array protection state for the program operation. It is assumed that the  $\text{EPEE}$  and  $\text{B0EPEE}$  inputs are setup prior to the assertion of  $\text{EHV}$ .

5. Read the UC3FCTL register until  $\text{HVS} = 0$ .
6. Read the UC3FCTL, confirm  $\text{PEGOOD} = 1$ .

7. Write EHV = 0.

### WARNING

Writing EHV = 0 before HVS = 0 causes the current program sequence to ABORT. The location for which the program sequence was aborted may not have been programmed with sufficient margins. The block containing that location must be erased and reprogrammed before that block of the UC3F array may be used reliably.

8. If more information needs to be programmed go to step 3.
9. Write SES = 0 in the UC3FCTL register.

**Figure 21-9. Program State Diagram**

**Table 21-7. Program Interlock State Descriptions**

| State | Mode                                                                                                          | Next State | Transition Requirement |                        |

**Table 21-7. Program Interlock State Descriptions (continued)**

| State | Mode                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | Next State | Transition Requirement |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| S2    | First Program Hardware Interlock Write:<br>Normal read operation still occurs. The array will accept programming writes. Accesses to the registers are normal register accesses. A write to UC3FCTL cannot change EHV at this time. If the write is to a register no data will be stored in the program data latch and the UC3F remains in state S2.                                                                                                                                                                                                                  | S1         | T1                     | Write SES = 0 or a reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | S3         | T3                     | Hardware Interlock. A successful write to any UC3F array location. This programming write will latch the selected word of data into the program data latch and the address is latched to select the location that will be programmed. Once a bit has been written then it remains in the program data latch until another write over-writes that data or a write of SES = 0. If the write is to a register no data will be stored in the program data latch and the UC3F remains in state S2. |
| S3    | Expanded Program Hardware Interlock Operation:<br>Programming writes are accepted so that data may be programmed. These writes may be to any UC3F array location. The location to be programmed is determined from the address initially written to on the first program interlock write. The program data latch may be updated on any program interlock writes which occur in this state. Accesses to the registers are normal register accesses. A write to UC3FCTL can change EHV. If the write is to a register no data will be stored in the program data latch. | S1         | T6                     | Write SES = 0 or a reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | S4         | T4                     | Write EHV = 1.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| S4    | Program Operation:<br>High voltage is applied to the array or shadow information to program the UC3F bit cells, and program margin reads are automatically performed by the internal program control logic. No further programming writes will be accepted. During programming, the array will not respond to any access. Accesses to the registers are allowed. A write to UC3FCTL can change EHV or HSUS only.                                                                                                                                                      | S1         | T5                     | Reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

|       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | S5         | T8                     | Write HSUS = 1 or disable the UC3F module.                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| S5    | Program Suspend Operation:<br>The program operation is suspended to either read the array or disable the module. Once HVS reads as a 0, the program operation is suspended. Normal reads to the array can be performed if the module is enabled; read accesses to the location being programmed returns indeterminate data.                                                                                                                                                                                                                                           | S1         | T10                    | Reset.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | S4         | T9                     | Write HSUS = 0 or re-enable the UC3F module.                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

### 21.3.7.2 Program Shadow Information

Programming the shadow information uses the same procedure as programming the array except that SIE must be set to a 1 prior to initiating the programming sequence. Only the lowermost addresses are used to encode words that get programmed in the shadow row. The shadow information is physically located in

lowest numbered block and will also be located in small block 0 if the lowest numbered block hosts a small block in the implemented configuration.

### 21.3.7.3 Program Suspend

The program operation may be suspended to allow read accesses to the array. Setting the HSUS bit in the UC3FCTL to a 1 while PE = 0, EHV = 1, and HVS = 1 forces the array into a program suspend state. The deassertion of the HVS bit (HVS = 0) signifies that the program operation has been successfully suspended. The HVS bit should negate within 10μs of asserting the HSUS bit.

While in program suspend mode, normal read accesses may be performed to the UC3F array or shadow information words. Reads to the array location targeted for program return indeterminate data since only a partial programming operation may have been performed.

The program operation may be resumed by setting HSUS = 0.

#### NOTE

Repeated suspending of a program operation to fetch array contents may extend the program operation. The internal program hardware may only resume the program operation at predefined steps of the internal program hardware sequence; interrupting the program operation on a high frequency basis may cause the internal program hardware to delay completion of the current step and delay advancement to the next step of the internal program hardware sequence. Frequent suspend/resume operations (more than approximately once per millisecond) may also cause program or erase timeouts, and are not recommended.

### 21.3.8 Erasing

To modify the charge stored in an isolated element of the UC3F bit from a logic 0 state to a logic 1 state, an erase operation is required. In the UC3F EEPROM, erase is a bulk operation that affects the stored charge of all the isolated elements in an array block. To make the UC3F module block-erasable, the array is divided into blocks that are physically isolated from each other. Each of the array blocks may be erased in isolation or in any combination. The UC3F array block size is fixed for all blocks in the module at 64 Kbytes and the module is comprised of eight blocks. Two of these blocks may be further subdivided into two small blocks. Array blocks of the UC3F EEPROM that are protected (PROTECT[M] = 1 or (SBEN[M] = 1 & SBPROTECT[M] = 1)) will not be erased. Also, if EPEE = 0 or B0EPEE = 0, no erase voltages will be applied to the array or the block corresponding to block 0 or small block 0 if SBEN[0] = 1.

The embedded program/erase algorithm first pre-programs all bits in blocks selected for erase prior to actually erasing the selected blocks.

The array blocks selected for erase operation are determined by BLOCK[0:7], SBBLOCK[0:1] in conjunction with SBEN[0:1], and the array configuration. If multiple blocks are selected for erase, the embedded erase hardware algorithm serially erases each array block until all of the selected blocks are erased. For instance, if BLOCK[0:7] = 0x78 and SBEN[0:1] = 0b00, then blocks 1, 2, 3, and 4 are selected for erase. The embedded erase hardware algorithm first erases block 1 and then erases block 2 followed

by blocks 3 and 4. The total erase time for this example is the block erase time,  $T_{ERASE}$ , multiplied by four since four blocks are erased. In addition, the preprogramming time to program all locations in blocks 1, 2, 3, and 4 to a “0” state needs to be considered when determining the total erase time. The preprogramming time is dependent on the data already stored in the Flash array before beginning the erase operation.

### 21.3.8.1 Erase Sequence

The UC3F EEPROM module requires a sequence of writes to the high voltage control register (UC3FCTL) and an erase interlock write in order to enable high voltage to the array and shadow information for erase operation. The required hardware algorithm erase sequence follows.

1. Write PROTECT[0:7] and SBPROTECT[0:1] to disable protect for the blocks to be erased.
2. Write BLOCK[0:7] and SBBLOCK[0:1] to select the blocks to be erased, PE = 1 and SES = 1 in the UC3FCTL register.

#### NOTE

BLOCK[0:7] and SBBLOCK[0:1] in conjunction with SBEN[0:1] determine which blocks are selected for erase. Blocks whose BLOCK bits or enabled small blocks whose SBBLOCK bits are set (equal to 1) get erased when an erase operation is performed.

3. Execute an erase interlock write to any UC3F array location.
4. Write EHV = 1 in the UC3FCTL register.

#### NOTE

The values of the EPEE and B0EPEE inputs are latched with the assertion of EHV to determine the array protection state for the erase operation. It is assumed that the EPEE and B0EPEE inputs are setup prior to the assertion of EHV.

5. Read the UC3FCTL register until HVS = 0.

#### WARNING

Writing EHV = 0 before HVS = 0 causes the current erase sequence to ABORT. All blocks being erased must go through another erase sequence before the UC3F EEPROM can be used reliably.

6. Read the UC3FCTL register. Confirm PEGOOD = 1.
7. Write EHV = 0 in the UC3FCTL register.
8. Write SES = 0 in the UC3FCTL register.

Table 21-8. Erase Interlock State Descriptions

| State | Mode                                                                                                                                                                                                                                                                                                                                                                                     | Next State | Transition Requirement                                                                                                                                                                                                    |
|-------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| S1    | Normal Operation:<br>Normal array reads and register accesses. The Block protect information can be modified.                                                                                                                                                                                                                                                                            | S2         | T2 Write PE = 1, SES = 1.                                                                                                                                                                                                 |
| S2    | Erase Hardware Interlock Write:<br>Normal read operation still occurs. The UC3F will accept the erase hardware interlock write. This write may be to any UC3F array location. Accesses to the registers are normal register accesses. A write to UC3FCTL cannot set EHV at this time. A write to the register is not an erase hardware interlock write and the UC3F remains in state S2. | S1         | T1 Write SES = 0 or a reset.                                                                                                                                                                                              |
|       |                                                                                                                                                                                                                                                                                                                                                                                          | S3         | T3 Hardware Interlock<br>A successful write to any UC3F array location is the erase interlock write. If the write is to a register the erase hardware interlock write has not been done and the UC3F remains in state S2. |
| S3    | High voltage write enable<br>Accesses to the registers are normal register accesses. A write to UC3FCTL can change SES or EHV.                                                                                                                                                                                                                                                           | S1         | T6 Write SES = 0 or a reset.                                                                                                                                                                                              |
|       |                                                                                                                                                                                                                                                                                                                                                                                          | S4         | T4 Write EHV = 1.                                                                                                                                                                                                         |
| S4    | Erase Operation:<br>High voltage is applied to the array blocks to erase the UC3F bit cells, and erase margin reads are automatically performed by the embedded erase control logic. During erase the array will not respond to any address. Accesses to the registers are allowed. A write to UC3FCTL can change EHV or HSUS only.                                                      | S1         | T5 Reset.                                                                                                                                                                                                                 |
|       |                                                                                                                                                                                                                                                                                                                                                                                          | S2         | T7 Write EHV = 0.                                                                                                                                                                                                         |
|       |                                                                                                                                                                                                                                                                                                                                                                                          | S5         | T8 Write HSUS = 1 or disable the UC3F module.                                                                                                                                                                             |

**Table 21-8. Erase Interlock State Descriptions (continued)**

| State | Mode                                                                                                                                                                                                                                                                                                                    | Next State | Transition Requirement |                                              |
|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|------------------------|----------------------------------------------|
| S5    | Erase Suspend Operation:<br>The erase operation is suspended to either read the array or disable the module. Once HVS reads as a 0, the erase operation is suspended. Normal reads to the array can be performed if the module is enabled; read accesses to locations in blocks being erased return indeterminate data. | S1         | T10                    | Reset.                                       |
|       |                                                                                                                                                                                                                                                                                                                         | S4         | T9                     | Write HSUS = 0 or re-enable the UC3F module. |

### 21.3.8.2 Erasing Shadow Information Words

The shadow information words are erased with either the lowest numbered block or small block 0, depending on the array configuration and the state of SBEN[0]. If the lowest numbered block in the array does not host a small block, then the shadow information words are erased with the lowest numbered block. If the lowest numbered block hosts a small block, then the shadow information words may get erased with small block 0. If SBEN[0] = 0 for this array configuration, then the shadow information words get erased with the lowest numbered block. If SBEN[0] = 1 for this same array configuration, then the shadow information words get erased with small block 0 only.

### 21.3.8.3 Erase Suspend

The erase operation may be suspended to allow read accesses to the array. Setting the HSUS bit in the UC3FCTL to a 1 while EHVS=1 and HVS=1 forces the array into an erase suspend state. The deassertion of the HVS bit (HVS = 0) signifies that the erase operation has been successfully suspended. The HVS bit should negate within 10 ms of asserting the HSUS bit.

While in erase suspend mode, normal read accesses may be performed to the UC3F array or shadow information words. Reads to the array block or blocks targeted for erase return indeterminate data since only a partial erase operation has been performed.

The erase operation may be resumed by setting HSUS = 0.

#### NOTE

Repeated suspending of an erase operation to fetch array contents may severely extend the erase operation. The internal erase hardware may only resume the erase operation at predefined steps of the internal erase hardware sequence; interrupting the erase operation on a high frequency basis may cause the internal erase hardware to delay completion of the current step and delay advancement to the next step of the internal erase hardware sequence.

### 21.3.9 Stop Operation

The UC3F EEPROM goes into a low power operation, or stop operation, while STOP = 1. When the STOP bit is set, only the control registers can be accessed on the UC3F EEPROM module. The UC3F EEPROM array may not be programmed, erased or read while STOP = 1.

With STOP = 1, the UC3F module enters a low power state by shutting down internal timers and bias generators. A stop recovery time of 1  $\mu$ s is required when clearing the STOP bit to exit stop operation. The BIU should allow 1  $\mu$ s following the negation of the STOP bit so that internal bias generators used by the array may recover to normal levels prior to initiating any UC3F array accesses.

#### NOTE

The UC3F cannot be stopped while the array is being programmed or erased since the STOP bit is write locked by SES = 1.

### 21.3.10 Disabled

The UC3F module can be disabled by clearing the FLEN bit in the IMMR register (see [Section 6.2.2, “System Configuration and Protection Registers”](#)). While disabled, the UC3F module is completely shut down. The register block and array are not accessible in this mode, and all circuits which draw any DC power are disabled to eliminate power consumption. In addition, the module can be disabled by setting the STOP bit in the UC3FMCR register (see [Section 21.2.1.2, “UC3F EEPROM Configuration Register \(UC3FMCR\)”](#)).

If the UC3F module is disabled while programming or erasing, the HSUS bit in the UC3FCTL register is asserted (HSUS = 1) to suspend the current program or erase operation. When the UC3F module is re-enabled, the suspended program or erase operation may be resumed by writing the HSUS bit to a 0.

#### NOTE

While there should be no harmful side effects resulting from disabling the UC3F module while in program or erase operation, it is not recommended that program or erase operation be suspended in this manner.

When disabled, the power used by the UC3F is reduced to leakage levels; otherwise, the UC3F module is enabled for accesses. For example, recovering from a stop operation (STOP = 1), there is a recovery time of 1  $\mu$ s for internal biases to reach to operating levels.

### 21.3.11 Censored Accesses and Non-Censored Accesses

The UC3F EEPROM has a censorship mechanism which provides for several censorship states. The censorship mechanism is used to increase restrictions in accessing Flash data. Four bits in UC3FMCR are used to configure the UC3F censorship state. These bits are:

- ACCESS—Enables a UC3F EEPROM to bypass the censorship.
- FIC—Overrides CENSOR[0:1] to force information censorship.
- CENSOR[0:1]—Determine the censorship state of the UC3F.

The device has two relevant modes used by the UC3F EEPROM to select the type of censorship. The first mode, which is uncensored mode, provides no censorship. In uncensored mode the ACCESS and CENSOR[0:1] bits are irrelevant. The second mode, censored mode, enables the UC3F EEPROM to exercise censorship based on the state of ACCESS, FIC, and CENSOR[0:1]. The device will enter censored mode only if one of following events occurs:

- booting from external memory

- operating in peripheral mode or upon any access by an external master
- operating in debug mode (BDM or Nexus)
- booting from internal SRAM

In censored mode, a UC3F EEPROM may disallow accesses to the array. If censored mode is entered by any means then the UC3F EEPROM will exercise censorship according to [Table 21-9](#).

**Table 21-9. Censorship States**

| ACCESS | FIC | CENSOR[0:1] | Description                                             |
|--------|-----|-------------|---------------------------------------------------------|
| 0      | 0   | 11          | Information censorship, No UC3F array accesses allowed. |
| 0      | 0   | 01 or 10    | No censorship, UC3F array accesses allowed.             |
| 0      | 0   | 00          | Cleared censorship, No UC3F array accesses allowed.     |
| 0      | 1   | XX          | Emulated censorship, No UC3F array accesses allowed.    |
| 1      | X   | XX          | No censorship, UC3F array accesses allowed.             |

While the device remains in the uncensored mode, ACCESS may be set to allow the device to enter censored mode and still access the UC3F array. ACCESS may not be set while the device is in censored mode but may be cleared.

Table 21-10. Censorship Modes and Censorship Status

| Mode                  | Censored |                |    |                        |    |                  | Uncensored |    |    |     |     |
|-----------------------|----------|----------------|----|------------------------|----|------------------|------------|----|----|-----|-----|
| ACCESS                | 0        |                |    |                        |    | 1                |            | 0  |    | 1   |     |
| FIC                   | 0        |                |    | 1                      |    | 0                | 1          | 0  | 1  | 0   | 1   |

| UC3F EEPROM<br>Status | #1       | #2             | #3 | #4                     | #5 | #6               | #7         | #8 | #9 | #10 | #11 |

 Indicates that the UC3F array cannot be accessed.

- ACCESS cannot be changed. FIC can be set. UC3F array cannot be accessed. CENSOR[0:1] can be set. CENSOR[0:1] cannot be cleared.
- ACCESS cannot be changed. FIC can be set. UC3F array can be accessed. CENSOR[0:1] can be set. CENSOR[0:1] can be cleared.
- ACCESS cannot be changed. FIC can be set. UC3F array cannot be accessed. CENSOR[0:1] cannot be cleared unless IWS = 1.
- ACCESS cannot be changed. FIC cannot be changed. UC3F array cannot be accessed. CENSOR[0:1] can be set. CENSOR[0:1] cannot be cleared unless IWS = 1.
- ACCESS cannot be changed. FIC cannot be changed. UC3F array cannot be accessed. CENSOR[0:1] cannot be cleared unless IWS = 1.
- ACCESS can be cleared. FIC can be set. UC3F array can be accessed. CENSOR[0:1] can be changed.
- ACCESS can be cleared. FIC cannot be changed. UC3F array can be accessed. CENSOR[0:1] can be changed.
- ACCESS can be changed. FIC can be set. UC3F array can be accessed. CENSOR[0:1] can be changed.
- ACCESS can be changed. FIC cannot be changed. UC3F array can be accessed. CENSOR[0:1] cannot be changed unless IWS = 1.
- ACCESS can be changed. FIC can be set. UC3F array can be accessed. CENSOR[0:1] can be changed.
- ACCESS can be changed. FIC cannot be changed. UC3F array can be accessed. CENSOR[0:1] can be changed.

The only way CENSOR[0:1] can be changed is by setting or clearing the FLASH NVM fuses. In the information censorship state, CENSOR[0:1] must be cleared to the cleared censorship state before CENSOR[0:1] can be put into the no censorship state. While clearing CENSOR[0:1] the entire UC3F array is erased. Thus the information stored in the UC3F array is made invalid while clearing CENSOR[0:1].

### 21.3.11.1 Setting and Clearing Censor

The value of each bit in CENSOR[0:1] is determined by the state of an NVM CAM cell. The NVM CAM cell is not writable but instead may be set or cleared. Reading CENSOR[0:1] while setting or clearing with the high voltage applied (CSC = 1 and EHV = 1) will return 0's.

### 21.3.11.2 Setting Sensor

The set operation changes the state in an NVM CAM cell from a 0 to a 1. This set operation can be done without changing the contents of the UC3F array. The required sequence to set one or both of the bits in CENSOR[0:1] follows.

1. Write CSC = 1, PE = 0 and SES = 1 in the UC3FCTL register
2. Write a 1 to the CENSOR bit(s) to be set
3. Write EHV = 1 in the UC3FCTL register
4. Read the UC3FCTL register until HVS = 0
5. Read the UC3FCTL register. Confirm PEGOOD = 1
6. Write EHV = 0 in the UC3FCTL register
7. Write SES = 0 and CSC = 0

### 21.3.11.3 Clearing Sensor

The clear operation changes the state of the CENSOR[0:1] bits from a 1 to a 0 by erasing the CAM cells. This clear operation can be done only while erasing the entire UC3F array and shadow information. The required sequence to clear CENSOR follows.

Clear CENSOR[0:1]

1. Write PROTECT[0:7] = 0x00 to enable the entire array for erase. If SBEN[M] = 1, then SBPROTECT[M] must also be cleared to 0.
2. Write BLOCK[0:7] = 0xFF, CSC = 1, PE = 1 and SES = 1 in the UC3FCTL register. If SBEN[M] = 1, then SBBLOCK[M] must also be set to 1.
3. Do an erase interlock write.

On the UC3F module, the erase interlock write can be performed in one of two ways, depending on the value of the UC3FCFIG bit 15, IWS.

If IWS = 0, a valid erase interlock write is a write to any valid array location. This is subject to any censorship conditions that might apply.

If IWS = 1, a valid erase interlock write can be a write to any valid array location or a write to the UC3FCMCR register.

When the IWS = 1, the CENSOR[0:1] bits can always be cleared in the UC3F flash EEPROM status states #3, #4 and #5 from [Table 21-10](#).

The erase interlock write is only valid if all blocks of the array are selected for erase and not protected. BLOCK[0:7] and SBBLOCK[0:1] set to 1, as well as PROTECT[0:7] and SBPROTECT[0:1] set to 0, are required for a valid erase interlock write during the clear sensor operation.

4. Write EHV = 1 in the UC3FCTL register.

### NOTE

The values of the EPEE and B0EPEE inputs are latched with the assertion of EHV to determine the array protection state for the clear sensor operation. It is assumed that the EPEE and B0EPEE inputs are setup prior to the assertion of EHV. If EPEE and B0EPEE are not enabled for erase, the CENSOR[0:1] bits may not be cleared.

5. Read the UC3FCTL register until HVS = 0.
6. Read the UC3FCTL register. Confirm PEGOOD = 1.
7. Write EHV = 0 in the UC3FCTL register.
8. Write SES = 0 and CSC = 0.

#### 21.3.11.4 Switching The UC3F EEPROM Sensorship

There are three states of sensorship that CENSOR[0:1] can select. These are—cleared sensorship, no sensorship (two states) and information sensorship. These three states, state values, transitions, and state of sensorship are shown in Figure 21-11.

Figure 21-11. Sensorship States and Transitions

CENSOR[0:1] transitions are listed as follows:

1. Cleared censorship to no censorship, T1  
Set CENSOR[0] or CENSOR[1].
2. No censorship to information censorship, T2  
Set CENSOR[0] and CENSOR[1].
3. Information censorship, no censorship or unknown to cleared censorship, T3  
Clear CENSOR[0:1]. This is done only while the entire UC3F array is erased.
4. Cleared censorship to information censorship, T4  
Set both CENSOR[0] and CENSOR[1].

### 21.3.12 Background Debug Mode or Freeze Operation

While in background debug mode, the UC3F should respond normally to accesses except that  $\overline{\text{LOCK}}$  is writable. See the  $\overline{\text{LOCK}}$  bit in [Table 21-3](#).

## Chapter 22

# CALRAM Operation

The calibration static random access memory (CALRAM) module provides the MPC561/MPC563 with a general purpose memory that may be read from or written to as either bytes, half-words, or words. In addition to this, a portion of the CALRAM, called the overlay region, can be used for calibration. Calibration in this context is defined as overlaying portions of the U-bus Flash with a portion of the CALRAM array. During normal Flash access, the RISC central processing unit (RPCU) reads data from U-bus Flash (through L-bus and L2U) as shown in [Figure 22-1](#). During calibration access, instead of Flash providing the data, the overlay regions of CALRAM provide the data to the RPCU.

### 22.1 Features

Standard CALRAM features are listed below:

- One-clock accesses
  - Two-cycle access for power savings
- Byte, half-word (16-bits), or word (32-bit) read/write accesses
- Each 8-Kbyte block has individual protection control bits.
- Low power standby operation for data retention

Special overlay features are:

- Eight overlay regions; each can be programmed to be 4-, 16-, 32-, 64-, 128-, 256-, or 512-bytes long
- Each overlay region size can be forced to 4 bytes long
- Data driven from the CALRAM module for overlay access has the same timing as the data that would have come from the U-bus Flash
- Overlay is for data read from the U-bus Flash space and does not affect instruction fetches from the Flash
- Overlay block is naturally aligned
  - For example, 128-byte block is 128-byte aligned
- Normal access to overlaid portion of CALRAM array can be made to generate an error (machine check) if so configured

## 22.2 CALRAM Block Diagram

Figure 22-1. System Block Diagram

## 22.3 CALRAM Memory Map

The MPC561/MPC563 chip internal memory map is shown in [Figure 22-2](#).

The CALRAM module is divided into two sections.

- Control section:
  - Includes all the registers in the CALRAM module
- Array sub-region:
  - Contains memory arrays

The MPC561/MPC563 contains one CALRAM module — a 32-Kbyte memory at address 0x3F 8000 – 0x3F FFFF as shown in [Figure 22-1](#) and [Figure 22-2](#). In addition, the module is assigned 16 32-bit register address spaces: 12 implemented and four unimplemented registers. The 12 implemented registers are: one module configuration register (CRAMMCR), one register reserved for factory test, eight region base address (CRAM\_RBx) registers, one overlay configuration register (CRAMOVLCR), and one ownership trace register (CALRAM\_OTR) to support a separate module called READI. Refer to [Chapter 24, “READI Module.”](#)

<sup>1</sup>NOTE: Available on MPC563 only

**Figure 22-2. MPC561/MPC563 Memory Map with CALRAM Address Ranges**

When the normal device power (VDD) is off, portions of the CALRAM array can be powered by separate power supply sources (IRAMSTBY) as shown in [Figure 22-3](#), thus allowing the data to be retained.

Figure 22-3. Standby Power Supply Configuration for CALRAM Array

## 22.4 Modes of Operation

The CALRAM module has the following modes of operation:

- Reset
- One-cycle
- Two-cycle
- Standby
- Stop
- Overlay

### 22.4.1 Reset

Reset configures the CALRAM module and resets some of the bits in the CALRAM registers to their default reset state. Some register bits are unaffected by reset. See section [Section 22.5, “Programming Model.”](#)

### 22.4.2 One-Cycle Mode

The CALRAM registers and array may be accessed for reads or writes as byte, (aligned) half-word, or word. This mode is the default mode of operation and, as the name suggests, the access time to the array and the internal registers for reads and writes is one cycle. Thus the one-cycle mode is used for high performance although it consumes more power than the two cycle mode.

#### 22.4.2.1 CALRAM Access/Privilege Violations

Each 8-Kbyte CALRAM array can be assigned read-only, data-only, or supervisor-only privilege if data relocate (DR) bit in the MSR is set. All CALRAM registers are assigned supervisor-only and data-only privilege. A privilege violation causes an error. See section [Section 22.5.1, “CALRAM Module Configuration Register \(CRAMMCR\).”](#)

An attempt to access any of the four unimplemented reserved registers (of the 16 register spaces) causes an error and returns 0's on the data bus for a read access. If an error condition occurs due to privilege violation or an attempt to access unimplemented portions of array or register space, then the type of the error generated depends on whether the access generating the error was initiated by the RCPU core or by a non-RCPU bus master. If the error causing access was initiated by the RCPU core, a data storage interrupt (DSI) is generated. If the access was initiated by a non-RCPU bus master, a machine check exception is generated. Also, a write access that generates an error does not corrupt the data in an array or a register. Similarly, a read access that generates an error does not drive the data on the L-bus from the array or the register, instead it drives 0's. Also, aborted accesses maintain data integrity. Aborted writes do not corrupt data in register/array, and aborted reads do not drive the requested data on L-bus.

### 22.4.3 Two-Cycle Mode

In this mode, the CALRAM module takes two cycles to complete an access and consumes less power than in one-cycle mode. It follows the normal one-cycle mode operation except that the accesses are completed one cycle later. This mode is selected by setting the 2CY bit in the CRAMMCR register.

### 22.4.4 Standby Operation/Keep-Alive Power

The registers and control logic for the CALRAM module are powered by VDD. The memory array is also supplied by VDD during normal operation; however, when the VDD is off, the CALRAM array is backed up by a switched source (IRAMSTBY) that is also known as standby power.

## 22.4.5 Stop Operation

The low power stop mode for this module is entered by setting the disable bit (DIS) in the CRAMMCR register. Reads from and writes to the array during this mode will generate an error.

When the disable bit (DIS) is cleared, the module returns to normal function.

## 22.4.6 Overlay Mode Operation

For a microcontroller used as a controller for an engine (or other electromechanical device), various parameters stored in the Flash memory may need to be changed in order to properly tune (calibrate) the engine. Because Flash memory may not be readily programmed during normal operation of an embedded controller, portions of the CALRAM array can be overlayed onto the U-bus Flash memory. By allowing the CALRAM module to overlay portions of Flash memory, parameters normally stored in the Flash may be tweaked and changed with a development tool both during normal operation and prior to programming a final, more precise version of the Flash memory.

The overlay is for read-only data and does not affect instruction fetches from the Flash. The data for any L-bus address which falls in the overlay region of the U-bus Flash will be driven by the CALRAM on the L-bus. The CALRAM also indicates to the L2U to block the data from the Flash to be driven onto the L-bus. As far as the RCPU core is concerned, the timing of data coming from the CALRAM appears to be the same as that from the Flash.

### 22.4.6.1 Overlay Mode Configuration

Each CALRAM module contains eight overlay regions, each of which is 512 bytes long as shown in [Figure 22-4](#). All overlay regions of a module are contiguous and each starts at the least significant address of the region and can increment all the way up to 512 bytes as shown in [Figure 22-5](#). As described in [Section 22.5.2, “CALRAM Region Base Address Registers \(CRAM\\_RBAX\)”](#), CRAM\_RBAX registers allow the programming of the base addresses RBA[11:29] of the U-bus Flash regions and the RGN\_SIZE[0:4] to be overlaid. Note that each region can also be individually disabled by writing 0000 to RGN\_SIZE[0:3]. If the programmed base address is not naturally aligned with respect to the RGN\_SIZE field, the least significant bits of the base address fields can be considered 0's in order to make the starting address naturally aligned. In an RBA register, RGN\_SIZE[0:3] = {0101} select the size to be 128 bytes, and even if CRAM\_RBAX [25:29] are not all 0's, they will be considered as 0's so that the address becomes 128-byte naturally aligned.

**Figure 22-4. CALRAM Array**

When programming the CRAM\_RBAX registers, the CALRAM can be put in overlay mode by setting the OVL bit in the CALRAM overlay configuration register (CRAMOVLCR) as described in section [Section 22.5.3, “CALRAM Overlay Configuration Register \(CRAM\\_OVLCR\).”](#) For example, [Figure 22-5](#) shows that overlay regions 0, 4, and 5 have their entire region of 512 bytes mapped to regions in the Flash as specified by CRAM\_RBA0, CRAM\_RBA4, and CRAM\_RBA5. Overlay region 1 is partially mapped to a region in Flash as specified by the CRAM\_RBA1. If the region size of 256 bytes is selected for overlay region 1, for example, then the enabled portion of overlay region 1 will occupy address 0x3F F200 to 0x3F F2FF. The rest of overlay region 1 from 0x3F F300 to 0x3F F3FF is available for normal (non-overlay) array access. Overlay regions 2, 3, 6, and 7 are disabled for overlay and hence can be used, in their entirety, for normal (non-overlay) array accesses.

CALRAM Operation

Figure 22-5. CALRAM Module Overlay Map of Flash (CLPS = 0)

Figure 22-6 illustrates the address spaces occupied by the two CALRAM modules available in MPC561/MPC563.

**Figure 22-6. CALRAM Address Map (CLPS = 0)**

If the CLPS bit in OVLCR register is set, then each of the eight region sizes is forced to be 4 bytes long as shown in [Figure 22-7](#), regardless of the value programmed in the RGN\_SIZE field. These 32 bytes occupy contiguous address space in CALRAM, for example, from 0x3F FFE0 to 0x3F FFFF. The remainder (4 Kbytes – 32 bytes) is not only available for normal array access but also contiguous with a 28-Kbyte non-overlay array.

**Figure 22-7. CALRAM Module Overlay Map of Flash (CLPS = 1)**

Figure 22-8 shows the overlay regions when the CLPS bit is set for CALRAM in MPC561/MPC563.

**Figure 22-8. CALRAM Address Map (CLPS = 1)**

The values programmed in the RBx registers are unaffected by reset. See [Section 22.5.2, “CALRAM Region Base Address Registers \(CRAM\\_RBx\)”](#) for details. On reset, it is not necessary to reprogram the RBx registers. In such cases, the calibration mode can be re-entered simply by setting the OVL bit.

### 22.4.6.2 Priority of Overlay Regions

When the address matches to more than one enabled portion of the overlay region, the effective region is the region with the highest priority. Priority is determined by the region number; the highest priority assigned to the lowest region number.

The benefit from this priority feature is that by storing the parameters in eight overlay regions, it overlays all eight regions onto the same 512-byte Flash region, and enables the overlay feature. Upon observing system performance with a set of parameters, the next set of parameters can be selected by simply disabling the highest priority region. This “observing and disabling the highest priority region” loop can continue until all regions are disabled. This allows moving from one set of parameters to another with

minimal amount of reprogramming efforts.

**Table 22-1. Priorities of Overlay Regions**

| Module/Region Number | Priority |
|----------------------|----------|
| CALRAM/region 0      | Highest  |
| CALRAM/region 1      | .        |
| CALRAM/region 2      | .        |
| CALRAM/region 3      | .        |
| CALRAM/region 4      | .        |
| CALRAM/region 5      | .        |
| CALRAM/region 6      | .        |
| CALRAM/region 7      | Lowest   |

### 22.4.6.3 Normal (Non-Overlay) Access to Overlay Regions

If overlay is enabled and CRAMOVLCR[DERR] is set, then any normal L-bus array access that falls within any of the eight enabled overlay regions generates a machine-check exception; otherwise the access terminates normally without asserting data error. The L-bus write accesses cause the data to be written regardless of whether the DERR bit is set or not.

For example, if overlay region 1 is programmed such that it is enabled and its region size is 256 bytes, then any L-bus access to address in the range of 0x3F F200 – 0x3F F2FF generates machine check exception if the DERR bit is set in CRAMOVLCR register. The other portion of region 1 from 0x3F F300 to 0x3F F3FF can be used as normal (non-overlay) array.

### 22.4.6.4 Calibration Write Cycle Flow

Write accesses to the overlaid U-bus Flash regions are ignored completely by the CALRAM module.

## 22.5 Programming Model

The following section describes the CALRAM programmer's model. The CALRAM has one register (CRAMMCR) for configuring the CALRAM array and one register dedicated to factory test. In addition, there are eight 32-bit region base address registers for calibration purposes and a 32-bit overlay configuration register. The region base address registers hold the base address for the Flash region and region size that need to be overlaid by the CALRAM. The overlay configuration register provides three bits (OVL, DERR, and CLSP) that are needed for overlay configuration. The CALRAM ownership trace register (CRAM\_OTR) is provided to support a separate module called a READI module. Access to all CALRAM registers requires the bus master to be in supervisor data mode. On a privilege violation, the register is not accessed and the access generates an error.

Table 22-2 shows the register address map for the MPC561/MPC563.

**Table 22-2. CALRAM Control Registers**

| Address   | Register          |
|-----------|-------------------|
| 0x38 0000 | CRAMMCR           |
| 0x38 0004 | for factory test  |
| 0x38 0008 | CRAM_RBA0         |
| 0x38 000C | CRAM_RBA1         |
| 0x38 0010 | CRAM_RBA2         |
| 0x38 0014 | CRAM_RBA3         |
| 0x38 0018 | CRAM_RBA4         |
| 0x38 001C | CRAM_RBA5         |
| 0x38 0020 | CRAM_RBA6         |
| 0x38 0024 | CRAM_RBA7         |
| 0x38 0028 | CRAMOVLCR         |
| 0x38 002C | CRAMOTR/READI_OTR |
| 0x38 0030 | Reserved          |
| 0x38 0034 | Reserved          |
| 0x38 0038 | Reserved          |
| 0x38 003C | Reserved          |

Any unimplemented bits in CALRAM registers return 0's on a read and writes to these bits are ignored.

### 22.5.1 CALRAM Module Configuration Register (CRAMMCR)

The module configuration register (CRAMMCR) contains bits that allow the CALRAM to be configured for normal RAM accesses.

**Figure 22-9. CALRAM Module Configuration Register (CRAMMCR)**

A brief description of each bit is provided in [Table 22-3](#)

**Table 22-3. CRAMMCR Bit Descriptions**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|------|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0    | LCK  | <p>Write protection — This bit is designed to lock out writes to the CRAMMCR. While LCK = 0 the register can be written repeatedly without restriction.</p> <p>If LCK = 1, the register does not accept writes (i.e., the value of the register remains unchanged, but the cycle terminates normally.)</p> <p>In normal mode, this bit can only be set once and can only be cleared by reset.</p> <p>0 writes to the CRAMMCR are unrestricted</p> <p>1 writes to the CRAMMCR are ignored</p> <p>In freeze mode, only the LCK bit may be written to zero if it was previously set.</p>                                                                                                                                                                                                                                                                                                                                          |
| 1    | DIS  | <p>Array disable — When set, this bit disables the CALRAM array.</p> <p>In this mode, all reads and writes to the CALRAM array are ignored and a bus error is generated. The CALRAM responds to register access while DIS = 1.</p> <p>This is a low power mode for the module, since all internal functions will be disabled.</p> <p>The module can be re-enabled by writing the DIS bit back to a zero. Reset will also re-enable the module.</p> <p>0 CALRAM module array access is enabled</p> <p>1 CALRAM module array access is disabled</p>                                                                                                                                                                                                                                                                                                                                                                              |
| 2    | 2CY  | <p>Two cycle mode — When set, this bit puts the CALRAM into a two cycle access mode operation for CALRAM register accesses as well as array accesses.</p> <p>This mode provides power savings by using the first cycle to decode any L-bus access for an address match to where the array resides.</p> <p>0 CALRAM module in one-cycle operation</p> <p>1 CALRAM module in two-cycle operation</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 3:19 | —    | Reserved                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 20   | R0   | <p>Read-only/read-write privilege — If the data relocate (DR) bit is set in Machine Status Register (MSR in RCPU) and R0 is also set, then write accesses are terminated with an error. If DR bit is 0, both reads and writes to the array block is allowed regardless of the value programmed in R0. This bit controls the highest 8-Kbyte block (lowest address) of CALRAM in the associated array. Likewise, R1, R2, and R3 control three other 8-Kbyte blocks in the same manner. See <a href="#">Table 22-4</a> for control bit address ranges.</p> <p>R0 = 0 and DR = 0 readable and writable (array 8-Kbyte block)</p> <p>R0 = 0 and DR = 1 readable and writable (array 8-Kbyte block)</p> <p>R0 = 1 and DR = 0 readable and writable (array 8-Kbyte block)</p> <p>R0 = 1 and DR = 1 read only (array 8-Kbyte block)</p>                                                                                               |
| 21   | D0   | <p>Data-only/data-instruction privilege (Data type assignment) — If the data relocate (DR) bit is set in Machine Status Register (MSR) and D0 is also set, then any access attempting to fetch an instruction from the array block generates an error. If DR bit is 0, both data read and instruction fetch from the array block is allowed, regardless of the value programmed in D0.</p> <p>This bit controls the highest 8-Kbyte block (lowest address) of CALRAM in the associated array. Likewise, D1, D2, and D3 control three other 8-Kbyte blocks in the same manner. See <a href="#">Table 22-4</a> for control bit address ranges.</p> <p>D0 = 0 and DR = 0 data and/or Instruction (array 8-Kbyte block)</p> <p>D0 = 0 and DR = 1 data and/or Instruction (array 8-Kbyte block)</p> <p>D0 = 1 and DR = 0 data and/or Instruction (array 8-Kbyte block)</p> <p>D0 = 1 and DR = 1 data only (array 8-Kbyte block)</p> |

**Table 22-3. CRAMMCR Bit Descriptions (continued)**

| Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

**Table 22-4. CRAMMCR Privilege Bit Assignment for 8-Kbyte Array Blocks**

| Bit Selection  | Address Block (Relative)  |
|----------------|---------------------------|
| R0, D0, and S0 | 0xFFFF 0000 – 0xFFFF 1FFF |
| R1, D1, and S1 | 0xFFFF 2000 – 0xFFFF 3FFF |
| R2, D2, and S2 | 0xFFFF 4000 – 0xFFFF 5FFF |
| R3, D3, and S3 | 0xFFFF 6000 – 0xFFFF 7FFF |

## 22.5.2 CALRAM Region Base Address Registers (CRAM\_RBx)

The region base address register defines the base address of a region on the U-bus Flash memory space that will be overlaid by a portion of the CALRAM memory space and the region size. Because eight such regions in the Flash can be overlaid by the CALRAM, eight such registers (x = 0, 1, 2, 7) are provided.

The CRAM\_RBx[11:29] provides the base address (starting address) of the of the U-bus Flash region to be overlaid and the CRAM\_RBx[0:3] provides size corresponding to the region. See [Table 22-6](#) for details. The RGN\_SIZE[0] is reserved and should never be programmed to a one, because the MPC563 has only 512 Kbytes of Flash, and CRAM\_RBx[11] and CRAM\_RBx[12] should never be programmed to a one. Also, note that if CRAM\_OVLCR[CLPS] is set, each of the eight sizes are forced

## CALRAM Operation

to be four bytes, regardless of the value programmed in the RGN\_SIZE[0:3] field. See [Section 22.5.3](#), “CALRAM Overlay Configuration Register (CRAM\_OVLCR)” for details.

The implemented bits of CRAM\_RBAX bits are unaffected by reset (hard reset). The diagram below shows one such register, CRAM\_RBA0, which provides the base address of overlay region 0.

**Figure 22-10. CALRAM Region Base Address Register (CRAM\_RBAX)**

**Table 22-5. CRAM\_RBAX Bit Descriptions**

| Bits  | Name     | Description                                                                                      |
|-------|----------|--------------------------------------------------------------------------------------------------|
| 0:3   | RGN_SIZE | These bits define the size of the overlay region. See <a href="#">Table 22-6</a> for sizes.      |
| 4:10  | —        | Reserved                                                                                         |
| 11:29 | RBA      | The region base address defines the starting address of the memory to be overlayed. <sup>1</sup> |
| 30:31 | —        | Reserved                                                                                         |

<sup>1</sup> The overlay match address will include ISB in its comparison. The overlay can only be in the range of the ISB internal space.

**Table 22-6. RGN\_SIZE Encoding**

| RGN_SIZE | Number of Overlay Bytes    |
|----------|----------------------------|
| 0000     | Overlay block disabled     |
| 0001     | Overlay block is 4 bytes   |
| 0010     | Overlay block is 16 bytes  |
| 0011     | Overlay block is 32 bytes  |
| 0100     | Overlay block is 64 bytes  |
| 0101     | Overlay block is 128 bytes |
| 0110     | Overlay block is 256 bytes |
| 0111     | Overlay block is 512 bytes |
| 1xxx     | Reserved                   |

**Note:** The overlay size of 8 bytes cannot be selected

## 22.5.4 CALRAM Ownership Trace Register (CRAM\_OTR)

This register is provided to support a separate module called READI. Refer to [Chapter 24, “READI Module.”](#)

The reads from this register will return 0’s.

### NOTE

CRAM\_OTR is also defined as READI\_OTR. See [Section 24.6.1.1, “User-Mapped Register \(OTR\).”](#)

CALRAM Operation

## Chapter 23

# Development Support

The visibility and controllability requirements of emulators and bus analyzers are in opposition to the trend of modern microcomputers and microprocessors where many bus cycles are directed to internal resources and are not visible externally.

In order to enhance the development tool visibility and controllability, some of the development support functions are implemented in silicon. These functions include program flow tracking, internal watchpoint, breakpoint generation, and emulation while in debug mode.

This section covers program flow tracking support, breakpoint/watchpoint support, development system interface support (debug mode) and software monitor debugger support. These features allow efficiency in debugging systems based on the MPC561/MPC563.

### 23.1 Program Flow Tracking

The mechanism described in this section allows tracking of program instruction flow with almost no performance degradation. The information provided may be compressed and captured externally and then parsed by a post-processing program using the microarchitecture defined below.

The program instructions flow is visible on the external bus when the MPC561/MPC563 is programmed to operate in serial mode and show all fetch cycles on the external bus. This mode is selected by programming the ISCT\_SER (instruction fetch show cycle control) field in the I-bus support control register (ICTRL), as shown in [Table 23-26](#). In this mode, the processor is fetch serialized, and all internal fetch cycles appear on the external bus. Processor performance is, therefore, much lower than when working in regular mode.

These features, together with the fact that most fetch cycles are performed internally (e.g., from the I-cache), increase performance but make it very difficult to provide the real program trace.

In order to reconstruct a program trace, the program code and the following additional information from the MCU are needed:

- A description of the last fetched instruction (stall, sequential, branch not taken, branch direct taken, branch indirect taken, exception taken)
- The addresses of the targets of all indirect flow change. Indirect flow changes include all branches using the link and count registers as the target address, all exceptions, and rfi, mtmsr and mtspr (to some registers) because they may cause a context switch.
- The number of instructions canceled each clock

Instructions are fetched sequentially until branches (direct or indirect) or exceptions appear in the program flow or some stall in execution causes the machine not to fetch the next address. Instructions may be architecturally executed, or they may be canceled in some stage of the machine pipeline.

The following sections define how this information is generated and how it should be used to reconstruct the program trace. The issue of data compression that could reduce the amount of memory needed by the debug system is also mentioned.

### 23.1.1 Program Trace Cycle

To allow visibility of the events happening in the machine a few dedicated pins are used and a special bus cycle attribute, program trace cycle, is defined.

The program trace cycle attribute is attached to all fetch cycles resulting from indirect flow changes. When program trace recording is needed, make sure these cycles are visible on the external bus.

The VSYNC indication, when asserted, forces all fetch cycles marked with the program trace cycle attribute to be visible on the external bus even if their data is found in one of the internal devices. To enable the external hardware to properly synchronize with the internal activity of the CPU, the assertion and negation of VSYNC forces the machine to synchronize. The first fetch after this synchronization is marked as a program trace cycle and is visible on the external bus. For more information on the activity of the external hardware during program trace refer to [Section 23.1.4, “External Hardware.”](#)

In order to keep the pin count of the chip as low as possible, VSYNC is not implemented as one of the chip’s external pins. It is asserted and negated using the serial interface implemented in the development port. For more information on this interface refer to [Section 23.4, “Development Port.”](#)

Forcing the CPU to show all fetch cycles marked with the program trace cycle attribute can be done either by asserting the VSYNC pin (as mentioned above) or by programming the fetch show cycle bits in the instruction support control register, ICTRL. For more information refer to [Section 23.1.5, “Instruction Fetch Show Cycle Control.”](#)

When the VSYNC indication is asserted, all fetch cycles marked with the program trace cycle attribute are made visible on the external bus. These cycles can generate regular bus cycles (address phase and data phase) when the instructions reside only in one of the external devices. Or, they can generate address-only cycles when the instructions reside in one of the internal devices (internal memory, etc.).

When VSYNC is asserted, some performance degradation is expected due to the additional external bus cycles. However, since this performance degradation is expected to be very small, it is possible to program the machine to show all indirect flow changes. In this way, the machine will always perform the additional external bus cycles and maintain exactly the same behavior both when VSYNC is asserted and when it is negated. For more information refer to [Section 23.6.10, “L-Bus Support Control Register 2.”](#)

The status pins are divided into two groups and one special case listed in the following sections.

#### 23.1.1.1 Instruction Queue Status Pins — VF [0:2]

Instruction queue status pins denote the type of the last fetched instruction or how many instructions were flushed from the instruction queue. These status pins are used for both functions because queue flushes only happen in clocks that there is no fetch type information to be reported.

Possible instruction types are defined in [Table 23-1](#).

**Table 23-1. VF Pins Instruction Encodings**

| VF[0:2] | Instruction Type                                                                                                                                                                   | VF Next Clock Will Hold              |
|---------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------|
| 000     | None                                                                                                                                                                               | More instruction type information    |
| 001     | Sequential                                                                                                                                                                         | More instruction type information    |
| 010     | Branch (direct or indirect) not taken                                                                                                                                              | More instruction type information    |
| 011     | VSYNC was asserted/negated and therefore the next instruction will be marked with the indirect change-of-flow attribute                                                            | More instruction type information    |
| 100     | Exception taken — the target will be marked with the indirect change-of-flow attribute                                                                                             | Queue flush information <sup>1</sup> |
| 101     | Branch indirect taken, rfi, mtmsr, isync and in some cases mtspr to CMPA-F, ICTRL, ECR, or DER — the target will be marked with the indirect change-of-flow attribute <sup>2</sup> | Queue flush information <sup>1</sup> |
| 110     | Branch direct taken                                                                                                                                                                | Queue flush information <sup>1</sup> |
| 111     | Branch (direct or indirect) not taken                                                                                                                                              | Queue flush information <sup>1</sup> |

<sup>1</sup> Unless next clock VF=111. See below.

<sup>2</sup> The sequential instructions listed here affect the machine in a manner similar to indirect branch instructions. Refer to [Section 23.1.3, “Sequential Instructions Marked as Indirect Branch.”](#)

[Table 23-2](#) shows VF[0:2] encodings for instruction queue flush information.

**Table 23-2. VF Pins Queue Flush Encodings**

| VF[0:2] | Queue Flush Information                       |
|---------|-----------------------------------------------|
| 000     | 0 instructions flushed from instruction queue |
| 001     | 1 instruction flushed from instruction queue  |
| 010     | 2 instructions flushed from instruction queue |
| 011     | 3 instructions flushed from instruction queue |
| 100     | 4 instructions flushed from instruction queue |
| 101     | 5 instructions flushed from instruction queue |
| 110     | Reserved                                      |
| 111     | Instruction type information <sup>1</sup>     |

<sup>1</sup> Refer to [Table 23-1](#).

### 23.1.1.2 History Buffer Flushes Status Pins— VFLS [0:1]

The history buffer flushes status pins denote how many instructions are flushed from the history buffer this clock due to an exception. [Table 23-3](#) shows VFLS encodings.

**Table 23-3. VFLS Pin Encodings**

| VFLS[0:1] | History Buffer Flush Information                                                                     |
|-----------|------------------------------------------------------------------------------------------------------|
| 00        | 0 instructions flushed from history queue                                                            |
| 01        | 1 instruction flushed from history queue                                                             |
| 10        | 2 instructions flushed from history queue                                                            |
| 11        | Used for debug mode indication (FREEZE). Program trace external hardware should ignore this setting. |

### 23.1.1.3 Queue Flush Information Special Case

There is one special case when although queue flush information is expected on the VF pins, (according to the last value on the VF pins), regular instruction type information is reported. The only instruction type information that can appear in this case is VF = 111, branch (direct or indirect) NOT taken. Since the maximum queue flushes possible is five, it is easy to identify this special case.

### 23.1.2 Program Trace when in Debug Mode

When entering debug mode an interrupt/exception taken is reported on the VF pins, (VF = 100) and a cycle marked with the program trace cycle is made visible externally.

When the CPU is in debug mode, the VF pins equal '000' and the VFLS pins equal '11'. For more information on debug mode refer to [Section 23.3, "Development System Interface."](#)

If VSYNC is asserted/negated while the CPU is in debug mode, this information is reported as the first VF pins report when the CPU returns to regular mode. If VSYNC was not changed while in debug mode, the first VF pins report will be of an indirect branch taken (VF = 101), suitable for the rfi instruction that is being issued. In both cases the first instruction fetch after debug mode is marked with the program trace cycle attribute and therefore is visible externally.

### 23.1.3 Sequential Instructions Marked as Indirect Branch

There are cases when non-branch (sequential) instructions may effect the machine in a manner similar to indirect branch instructions. These instructions include rfi, mtmsr, isync and mtspr to CMPA-F, ICTRL, ECR and DER.

These instructions are marked by the CPU as indirect branch instructions (VF = 101) and the following instruction address is marked with the same program trace cycle attribute as if it were an indirect branch target. Therefore, when one of these special instructions is detected in the CPU, the address of the following instruction is visible externally. In this way the reconstructing software is able to evaluate correctly the effect of these instructions.

### 23.1.4 External Hardware

When program trace is needed, the external hardware needs to sample the status pins (VF and VFLS) each clock cycle and the address of all cycles marked with the program trace cycle attribute.

Program trace can be used in various ways. Below are two examples of how program trace can be used:

- **Back trace** — Back trace is useful when a record of the program trace before some event occurred is needed. An example of such an event is some system failure.  
In case back trace is needed the external hardware should start sampling the status pins (VF and VFLS) and the address of all cycles marked with the program trace cycle attribute immediately when reset is negated. If show cycles is programmed out of reset to show all, all cycles marked with program trace cycle attribute are visible on the external bus. VSYNC should be asserted sometime after reset and negated when the programmed event occurs. If no show is programmed for show cycles, make sure VSYNC is asserted before the Instruction show cycles programming is changed from show all.  
Note that in case the timing of the programmed event is unknown it is possible to use cyclic buffers. After VSYNC is negated the trace buffer will contain the program flow trace of the program executed before the programmed event occurred.
- **Window trace** — Window trace is useful when a record of the program trace between two events is needed. In case window trace is needed the VSYNC pin should be asserted between these two events.  
After the VSYNC pin is negated the trace buffer will contain information describing the program trace of the program executed between the two events.

#### 23.1.4.1 Synchronizing the Trace Window to the CPU Internal Events

The assertion/negation of VSYNC is done using the serial interface implemented in the development port. In order to synchronize the assertion/negation of VSYNC to an internal event of the CPU, it is possible to use the internal breakpoints together with debug mode. This method is available only when debug mode is enabled. For more information on debug mode refer to [Section 23.3, “Development System Interface.”](#)

The following is an example of steps that enable synchronization of the trace window to the CPU internal events:

1. Enter debug mode, either immediately out of reset or using the debug mode request
2. Program the hardware to break on the event that marks the start of the trace window using the control registers defined in [Section 23.2, “Watchpoints and Breakpoints Support”](#)
3. Enable debug mode entry for the programmed breakpoint in the debug enable register (DER). See [Section 23.6.13, “Development Port Data Register \(DPDR\)”](#)
4. Return to the regular code run (see [Section 23.3.1.6, “Exiting Debug Mode”](#))
5. The hardware generates a breakpoint when the programmed event is detected and the machine enters debug mode (see [Section 23.3.1.2, “Entering Debug Mode”](#))
6. Program the hardware to break on the event that marks the end of the trace window
7. Assert VSYNC
8. Return to the regular code run. The first report on the VF pins is a VSYNC (VF = 011).
9. The external hardware starts sampling the program trace information upon the report on the VF pins of VSYNC
10. The hardware generates a breakpoint when the programmed event is detected and the machine enters debug mode

11. Negate VSYNC
12. Return to the regular code run (issue an rfi). The first report on the VF pins is a VSYNC (VF = 011)
13. The external hardware stops sampling the program trace information upon the report on the VF pins of VSYNC

#### 23.1.4.2 Detecting the Trace Window Start Address

When using back trace, latching the value of the status pins (VF and VFLS), and the address of the cycles marked as program trace cycle, should start immediately after the negation of reset. The start address is the first address in the program trace cycle buffer.

When using window trace, latching the value of the status pins (VF and VFLS), and the address of the cycles marked as program trace cycle, should start immediately after the first VSYNC is reported on the VF pins. The start address of the trace window should be calculated according to first two VF pins reports.

Assuming that VF1 and VF2 are the two first VF pins reports and T1 and T2 are the two addresses of the first two cycles marked with the program trace cycle attribute that were latched in the trace buffer, use the following table to calculate the trace window start address.

**Table 23-4. Detecting the Trace Buffer Start Point**

| VF1          | VF2                          | Starting point              | Description                                                                                                |
|--------------|------------------------------|-----------------------------|------------------------------------------------------------------------------------------------------------|
| 011<br>VSYNC | 001<br>sequential            | T1                          | VSYNC asserted followed by a sequential instruction. The start address is T1                               |
| 011<br>VSYNC | 110<br>branch direct taken   | T1 - 4 +<br>offset (T1 - 4) | VSYNC asserted followed by a taken direct branch. The start address is the target of the direct branch     |
| 011<br>VSYNC | 101<br>branch indirect taken | T2                          | VSYNC asserted followed by a taken indirect branch. The start address is the target of the indirect branch |

#### 23.1.4.3 Detecting the Assertion/Negation of VSYNC

Since the VF pins are used for reporting both instruction type information and queue flush information, the external hardware must take special care when trying to detect the assertion/negation of VSYNC. When VF = 011 it is a VSYNC assertion/negation report only if the previous VF pins value was one of the following values: 000, 001, or 010.

#### 23.1.4.4 Detecting the Trace Window End Address

The information on the status pins that describes the last fetched instruction and the last queue/history buffer flushes, changes every clock. Cycles marked as program trace cycle are generated on the external bus only when possible (when the SIU wins the arbitration over the external bus). Therefore, there is some delay between the information reported on the status pins that a cycle marked as program trace cycle will be performed on the external bus and the actual time that this cycle can be detected on the external bus.

When VSYNC is negated (through the serial interface of the development port), the CPU delays the report of the of the assertion/negation of VSYNC on the VF pins (VF = 011) until all addresses marked with the program trace cycle attribute were visible externally. Therefore, the external hardware should stop

sampling the value of the status pins (VF and VFLS), and the address of the cycles marked as program trace cycle immediately after the VSYNC report on the VF pins.

The last two instructions reported on the VF pins are not always valid. Therefore at the last stage of the reconstruction software, the last two instructions should be ignored.

### 23.1.4.5 Compress

In order to store all the information generated on the pins during program trace (five bits per clock + 30 bits per show cycle) a large memory buffer may be needed. However, since this information includes events that were canceled, compression can be very effective. External hardware can be added to eliminate all canceled instructions and report only on branches (taken and not taken), indirect flow change, and the number of sequential instructions after the last flow change.

## 23.1.5 Instruction Fetch Show Cycle Control

Instruction fetch show cycles are controlled by the bits in the ICTRL and the state of VSYNC. The following table defines the level of fetch show cycles generated by the CPU. For information on the fetch show cycles control bits refer to [Table 23-5](#).

**Table 23-5. Fetch Show Cycles Control**

| VSYNC | ISCTL<br>Instruction Fetch Show Cycle<br>Control Bits | Show Cycles Generated                  |
|-------|-------------------------------------------------------|----------------------------------------|
| X     | 00                                                    | All fetch cycles                       |
| X     | 01                                                    | All change of flow (direct & indirect) |
| X     | 10                                                    | All indirect change of flow            |
| 0     | 11                                                    | No show cycles are performed           |
| 1     | 11                                                    | All indirect change of flow            |

### NOTE

A cycle marked with the program trace cycle attribute is generated for any change in the VSYNC state (assertion or negation).

## 23.2 Watchpoints and Breakpoints Support

Watchpoints, when detected, are reported to the external world on dedicated pins but do not change the timing and the flow of the machine. Breakpoints, when detected, force the machine to branch to the appropriate exception handler. The RCPU supports internal watchpoints, internal breakpoints, and external breakpoints.

Internal watchpoints are generated when a user programmable set of conditions are met. Internal breakpoints can be programmed to be generated either as an immediate result of the assertion of one of the internal watchpoints, or after an internal watchpoint is asserted for a user programmable times. Programming a certain internal watchpoint to generate an internal breakpoint can be done either in

software, by setting the corresponding software trap enable bit, or on the fly using the serial interface implemented in the development port to set the corresponding development port trap enable bit.

External breakpoints can be generated by any of the peripherals of the system, including those found on the MPC561/MPC563 or externally, and also by an external development system. Peripherals found on the external bus use the serial interface of the development port to assert the external breakpoint.

In the RCPU, as in other RISC processors, saving/restoring machine state on the stack during exception handling, is done mostly in software. When the software is in the middle of saving/restoring machine state, MSR[RI] is cleared. Exceptions that occur and that are handled by the RCPU when MSR[RI] is clear result in a non-restartable machine state. For more information refer to [Section 3.13.4, “Exceptions.”](#)

In general, breakpoints are recognized in the RCPU only when MSR[RI] is set, which guarantees machine restartability after a breakpoint. In this working mode breakpoints are said to be masked. There are cases when it is desired to enable breakpoints even when MSR[RI] is clear, with the possible risk of causing a non-restartable machine state. Therefore internal breakpoints have also a programmable non-masked mode, and an external development system can also choose to assert a non-maskable external breakpoint.

Watchpoints are not masked and therefore always reported on the external pins, regardless of the value of MSR[RI]. The counters, although counting watchpoints, are part of the internal breakpoints logic and therefore are not decremented when the RCPU is operating in the masked mode and MSR[RI] is clear.

[Figure 23-1](#) shows the watchpoint and breakpoint support of the RCPU.

Figure 23-1. Watchpoint and Breakpoint Support in the CPU

## 23.2.1 Internal Watchpoints and Breakpoints

This section describes the internal breakpoints and watchpoints support of the RCPU. For information on external breakpoints support refer to [Section 23.3, “Development System Interface.”](#)

Internal breakpoint and watchpoint support is based on eight comparators comparing information on instruction and load/store cycles, two counters, and two AND-OR logic structures. The comparators perform compare on the Instruction address (I-address), on the load/store address (L-address) and on the load/store data (L-data).

The comparators are able to detect the following conditions: equal, not equal, greater than, less than (greater than or equal and less than or equal are easily obtained from these four conditions; for more information refer to [Section 23.2.1.6, “Generating Six Compare Types”](#)). Using the AND-OR logic structures “in range” and “out of range” detections (on address and on data) are supported. Using the counters, it is possible to program a breakpoint to be recognized after an event was detected a predefined number of times.

The L-data comparators can operate on fix point data of load or store. When operating on fix point data the L-data comparators are able to perform compare on bytes, half-words and words and can treat numbers either as signed or as unsigned values.

The comparators generate match events. The match events enter the instruction AND-OR logic where the instruction watchpoints and breakpoint are generated. The instruction watchpoints, when asserted, may generate the instruction breakpoint. Two of them may decrement one of the counters. If one of the instruction watchpoints expires in a counter that is counting, the instruction breakpoint is asserted.

The instruction watchpoints and the load/store match events (address and data) enter the load/store AND-OR logic where the load/store watchpoints and breakpoint are generated. The load/store watchpoints, when asserted, may generate the load/store breakpoint or they may decrement one of the counters. When a counter that is counting one of the load/store watchpoints expires, the load/store breakpoint is asserted.

Watchpoints progress in the machine and are reported on retirement. Internal breakpoints progress in the machine until they reach the top of the history buffer when the machine branches to the breakpoint exception routine.

In order to enable the use of the breakpoint features without adding restrictions on the software, the address of the load/store cycle that generated the load/store breakpoint is not stored in the DAR (data address register), like other load/store type exceptions. In case of a load/store breakpoint, the address of the load/store cycle that generated the breakpoint is stored in an implementation-dependent register called the BAR (breakpoint address register).

Key features of internal watchpoint and breakpoint support are:

- Four I-address comparators (each supports equal, not equal, greater than, less than)
- Two L-address comparators (each supports equal, not equal, greater than, less than) including least significant bits masking according to the size of the bus cycle for the byte and half-word working modes. Refer to [Section 23.2.1.2, “Byte and Half-Word Working Modes.”](#)
- Two L-data comparators (each supports equal, not equal, greater than, less than) including byte, half-word and word operating modes and four byte mask bits for each comparator. Can be used for fix point data. Match is detected only on the valid part of the data bus (according to the cycle’s size and the two address least significant bits).
- No internal breakpoint/watchpoint matching support for unaligned words and half-words
- The L-data comparators can be programmed to treat fix point numbers as signed values or as unsigned values
- Combine comparator pairs to detect in and out of range conditions (including either signed or unsigned values on the L-data)
- A programmable AND-OR logic structure between the four instruction comparators results with five outputs, four instruction watchpoints and one instruction breakpoint
- A programmable AND-OR logic structure between the four instruction watchpoints and the four load/store comparators results with three outputs, two load/store watchpoints and one load/store breakpoint
- Five watchpoint pins, three for the instruction and two for the load/store
- Two dedicated 16-bit down counters. Each can be programmed to count either an instruction watchpoint or an load/store watchpoint. Only architecturally executed events are counted, (count up is performed in case of recovery).

- On the fly trap enable programming of the different internal breakpoints using the serial interface of the development port (refer to [Section 23.4, “Development Port”](#)). Software control is also available.
- Watchpoints do not change the timing of the machine
- Internal breakpoints and watchpoints are detected on the instruction during instruction fetch
- Internal breakpoints and watchpoints are detected on the load/store during load/store bus cycles
- Both instruction and load/store breakpoints and watchpoints are handled and reported on retirement. Breakpoints and watchpoints on recovered instructions (as a result of exceptions, interrupts or miss prediction) are not reported and do not change the timing of the machine.
- Instructions with instruction breakpoints are not executed. The machine branches to the breakpoint exception routine BEFORE it executes the instruction.
- Instructions with load/store breakpoints are executed. The machine branches to the breakpoint exception routine AFTER it executes the instruction. The address of the access is placed in the BAR (breakpoint address register).
- Load/store multiple and string instructions with load/store breakpoints first finish execution (all of it) and then the machine branches to the breakpoint exception routine.
- Load/store data compare is done on the load/store, AFTER swap in store accesses and BEFORE swap in load accesses (as the data appears on the bus).
- Internal breakpoints may operate either in masked mode or in non-masked mode.
- Both “go to x” and “continue” working modes are supported for the instruction breakpoints.

### 23.2.1.1 Restrictions

There are cases when the same watchpoint can be detected more than once during the execution of a single instruction, e.g. a load/store watchpoint is detected on more than one transfer when executing a load/store multiple/string or a load/store watchpoint is detected on more than one byte when working in byte mode. In all these cases only one watchpoint of the same type is reported for a single instruction. Similarly, only one watchpoint of the same type can be counted in the counters for a single instruction.

Because watchpoint events are reported upon the retirement of the instruction that caused the event, and more than one instruction can retire from the machine in one clock, consequent events may be reported in the same clock. Moreover the same event, if detected on more than one instruction (e.g., tight loops, range detection), in some cases will be reported only once. Note that the internal counters count correctly in these cases.

Do not put a breakpoint on an mtspr instruction that accesses the ICTRL register when ICTRL[IFM] = 1 because this causes unpredictable behavior.

### 23.2.1.2 Byte and Half-Word Working Modes

The CPU watchpoints and breakpoints support enables detection of matches on bytes and half-words even when accessed using a load/store instruction of larger data widths, for example when loading a table of bytes using a series of load word instructions. In order to use this feature, program the byte mask for each of the L-data comparators and to write the needed match value to the correct half-word of the data

comparator when working in half-word mode and to the correct bytes of the data comparator when working in byte mode.

Since bytes and half-words can be accessed using a larger data width instruction, it is impossible to predict the exact value of the L-address lines when the requested byte/half-word is accessed, (e.g., if the matched byte is byte two of the word and it is accessed using a load word instruction), the L-address value will be of the word (byte zero). Therefore, the CPU masks the two least-significant bits of the L-address comparators whenever a word access is performed and the least-significant bit whenever a half-word access is performed.

Address range is supported only when aligned according to the access size. (See [Section 23.2.1.3](#), “Examples”).

### 23.2.1.3 Examples

- A fully supported scenario:
  - Looking for:
    - Data size: Byte
    - Address: 0x00000003
    - Data value: greater than 0x07 and less than 0x0c
  - Programming options:
    - One L-address comparator = 0x00000003 and program for equal
    - One L-data comparator = 0x00000007 and program for greater than
    - One L-data comparator = 0x0000000c and program for less than
    - Both byte masks = 0xe
    - Both L-data comparators program to byte mode
  - Result:
    - The event will be correctly detected regardless of the load/store instruction the compiler chooses for this access
- A fully supported scenario:
  - Looking for:
    - Data size: half-word
    - Address: greater than 0x00000000 and less than 0x0000000c
    - Data value: greater than 0x4e204e20 and less than 0x9c409c40
  - Programming option:
    - One L-address comparator = 0x00000000 and program for greater than
    - One L-address comparator = 0x0000000c and program for less than
    - One L-data comparator = 0x4e204e20 and program for greater than
    - One L-data comparator = 0x9c409c40 and program for less than
    - Both byte masks = 0x0
    - Both L-data comparators program to half-word mode
  - Result:
    - The event will be correctly detected as long as the compiler does not use a load/store instruction with data size of byte.

- A partially supported scenario:
  - Looking for:
    - Data size: half-word
    - Address: greater than or equal 0x00000002 and less than 0x0000000e
    - Data value: greater than 0x4e204e20 and less than 0x9c409c40
  - Programming option:
    - One L-address comparator = 0x00000001 and program for greater than
    - One L-address comparator = 0x0000000e and program for less than
    - One L-data comparator = 0x4e204e20 and program for greater than
    - One L-data comparator = 0x9c409c40 and program for less than
    - Both byte masks = 0x0
    - Both L-data comparators program to half-word mode or to word mode
  - Result:
 

The event will be correctly detected if the compiler chooses a load/store instruction with data size of half-word. If the compiler chooses load/store instructions with data size greater than half-word (word, multiple), there might be some false detections.

These can be ignored only by the software that handles the breakpoints. The following figure illustrates this partially supported scenario.

Possible false detect on these half-words when using word/multiple

**Figure 23-2. Partially Supported Watchpoint/Breakpoint Example**

### 23.2.1.4 Context Dependent Filter

The CPU can be programmed to either recognize internal breakpoints only when the recoverable interrupt bit in the MSR is set (masked mode) or it can be programmed to always recognize internal breakpoints (non-masked mode).

When the CPU is programmed to recognize internal breakpoints only when MSR[RI] = 1, it is possible to debug all parts of the code except when the machine status save/restore registers (SRR0 and SRR1), DAR (data address register) and DSISR (data storage interrupt status register) are busy and, therefore, MSR[RI] = 0, (in the prologues and epilogues of interrupt/exception handlers).

When the CPU is programmed always to recognize internal breakpoints, it is possible to debug all parts of the code. However, if an internal breakpoint is recognized when MSR[RI] = 0 (SRR0 and SRR1 are busy), the machine enters into a non-restartable state. For more information refer to [Section 3.13.4, “Exceptions.”](#)

When working in the masked mode, all internal breakpoints detected when  $MSR[RI] = 0$  are lost. Watchpoints detected in this case are not counted by the debug counters. Watchpoints detected are always reported on the external pins, regardless of the value of  $MSR[RI]$ .

Out of reset, the CPU is in masked mode. Programming the CPU to be in non-masked mode is done by setting the BRKNOMSK bit in the LCTRL2 register. Refer to [Section 23.6.10, “L-Bus Support Control Register 2.”](#) The BRKNOMSK bit controls all internal breakpoints (I-breakpoints and L-breakpoints).

### 23.2.1.5 Ignore First Match

In order to facilitate the debugger utilities “continue” and “go from x”, the ignore first match option is supported for instruction breakpoints. When an instruction breakpoint is first enabled (as a result of the first write to the instruction support control register or as a result of the assertion of  $MSR[RI]$  when operating in the masked mode), the first instruction will not cause an instruction breakpoint if the ignore first match (IFM) bit in the instruction support control register (ICTRL) is set (used for “continue”).

When the IFM bit is clear, every matched instruction can cause an instruction breakpoint (used for “go from x”). This bit is set by the software and cleared by the hardware after the first instruction breakpoint match is ignored. Load/store breakpoints and all counter generated breakpoints (instruction and load/store) are not affected by this mode.

### 23.2.1.6 Generating Six Compare Types

Using the four compare types mentioned above (equal, not equal, greater than, less than) it is possible to generate also two more compare types: greater than or equal and less than or equal.

- Generating the greater than or equal compare type can be done by using the greater than compare type and programming the comparator to the needed value minus 1.
- Generating the less than or equal compare type can be done by using the less than compare type and programming the comparator to the needed value plus 1.

This method does not work for the following boundary cases:

- Less than or equal of the largest unsigned number (1111...1)
- Greater than or equal of the smallest unsigned number (0000...0)
- Less than or equal of the maximum positive number when in signed mode (0111...1)
- Greater than or equal of the maximum negative number when in signed mode (1000...)

These boundary cases need no special support because they all mean ‘always true’ and can be programmed using the ignore option of the load/store watchpoint programming (refer to [Section 23.2, “Watchpoints and Breakpoints Support”](#)).

## 23.2.2 Instruction Support

There are four instruction address comparators A,B,C, and D. Each is 30 bits long, generating two output signals: equal and less than. These signals are used to generate one of the following four events: equal, not equal, greater than, less than.

The instruction watchpoints and breakpoint are generated using these events and according to user programming. Note that using the OR option enables “out of range” detect.

**Table 23-6. Instruction Watchpoints Programming Options**

| Name | Description                   | Programming Options                |
|------|-------------------------------|------------------------------------|
| IWP0 | First instruction watchpoint  | Comparator A<br>Comparators (A&B)  |
| IWP1 | Second instruction watchpoint | Comparator B<br>Comparator (A   B) |
| IWP2 | Third instruction watchpoint  | Comparator C<br>Comparators (C&D)  |
| IWP3 | Fourth instruction watchpoint | Comparator D<br>Comparator (C   D) |

**Figure 23-3. Instruction Support General Structure**

### 23.2.2.1 Load/Store Support

There are two load/store address comparators E, and F. Each compares the 32 address bits and the cycle's attributes (read/write). The two least-significant bits are masked (ignored) whenever a word is accessed and the least-significant bit is masked whenever a half-word is accessed. (For more information refer to [Section 23.2.1.2, "Byte and Half-Word Working Modes"](#)). Each comparator generates two output signals: equal and less than. These signals are used to generate one of the following four events (one from each comparator): equal, not equal, greater than, less than.

There are two load/store data comparators (comparators G,H) each is 32 bits wide and can be programmed to treat numbers either as signed values or as unsigned values. Each data comparator operates as four independent byte comparators. Each byte comparator has a mask bit and generates two output signals: equal and less than, if the mask bit is not set. Therefore, each 32 bit comparator has eight output signals.

These signals are used to generate the "equal and less than" signals according to the compare size programmed (byte, half-word, word). When operating in byte mode all signals are significant, when operating in half-word mode only four signals from each 32 bit comparator are significant. When operating in word mode only two signals from each 32 bit comparator are significant.

From the new "equal and less than" signals and according to the compare type programmed one of the following four match events are generated: equal, not equal, greater than, less than. Therefore, from the two 32-bit comparators eight match indications are generated: Gmatch[0:3], Hmatch[0:3].

According to the lower bits of the address and the size of the cycle, only match indications that were detected on bytes that have valid information are validated, the rest are negated. Note that if the cycle executed has a smaller size than the compare size (e.g., a byte access when the compare size is word or half-word) no match indication will be asserted.

Using the match indication signals four load/store data events are generated in the following way.

**Table 23-7. Load/Store Data Events**

| Event Name | Event Function <sup>1</sup>                                                             |
|------------|-----------------------------------------------------------------------------------------|
| G          | (Gmatch0   Gmatch1   Gmatch2   Gmatch3)                                                 |
| H          | (Hmatch0   Hmatch1   Hmatch2   Hmatch3)                                                 |
| (G&H)      | ((Gmatch0 & Hmatch0)   (Gmatch1 & Hmatch1)   (Gmatch2 & Hmatch2)   (Gmatch3 & Hmatch3)) |
| (G   H)    | ((Gmatch0   Hmatch0)   (Gmatch1   Hmatch1)   (Gmatch2   Hmatch2)   (Gmatch3   Hmatch3)) |

<sup>1</sup> '&' denotes a logical AND, '|' denotes a logical OR

The four load/store data events together with the match events of the load/store address comparators and the instruction watchpoints are used to generate the load/store watchpoints and breakpoint according to the programming.

**Table 23-8. Load/Store Watchpoints Programming Options**

| Name | Description                  | Instruction Events Programming Options            | L-address Events Programming Options                                                             | L-data Events Programming Options                                                                |
|------|------------------------------|---------------------------------------------------|--------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------|
| LWP0 | First Load/store watchpoint  | IWP0, IWP1, IWP2, IWP3, ignore instruction events | Comparator E<br>Comparator F<br>Comparators (E&F)<br>Comparators (E   F)<br>ignore L-addr events | Comparator G<br>Comparator H<br>Comparators (G&H)<br>Comparators (G   H)<br>ignore L-data events |
| LWP1 | Second Load/store watchpoint | IWP0, IWP1, IWP2, IWP3, ignore instruction events | Comparator E<br>Comparator F<br>Comparators (E&F)<br>Comparators (E   F)<br>ignore L-addr events | Comparator G<br>Comparator H<br>Comparators (G&H)<br>Comparators (G   H)<br>ignore L-data events |

Note that when programming the load/store watchpoints to ignore L-addr events and L-data events, it does not reduce the load/store watchpoints detection logic to be instruction watchpoint detection logic since the instruction must be a load/store instruction for the load/store watchpoint event to trigger.

Figure 23-4. Load/Store Support General Structure

### 23.2.3 Watchpoint Counters

There are two 16-bit watchpoint counters. Each counter is able to count one of the instruction watchpoints or one of the load/store watchpoints. Both generate the corresponding breakpoint when they reach ZERO.

When working in the masked mode, the counters do not count watchpoints detected when  $MSR[RI] = 0$ . See [Section 23.2.1.4, “Context Dependent Filter.”](#)

The counters value when counting watchpoints programmed on the actual instructions that alter the counters, are not predictable. Reading values from the counters when they are active, must be synchronized by inserting a sync instruction before the actual read is performed.

#### NOTE

When programmed to count instruction watchpoints, the last instruction which decrements the counter to ZERO is treated like any other instruction breakpoint in the sense that it is not executed and the machine branches to the breakpoint exception routine BEFORE it executes this instruction. As a side effect of this behavior, the value of the counter inside the breakpoint exception routine equals ONE and not ZERO as might be expected.

When programmed to count load/store watchpoints, the last instruction which decrements the counter to ZERO is treated like any other load/store breakpoint in the sense that it is executed and the machine branches to the breakpoint exception routine AFTER it executes this instruction. Therefore, the value of the counter inside the breakpoint exception routine equals ZERO.

#### 23.2.3.1 Trap Enable Programming

The trap enable bits can be programmed by regular software (only if  $MSR[PR] = 0$ ) using the `mtspr` instruction or “on the fly” using the special development port interface. For more information refer to section [Section 23.4.6.5, “Development Port Serial Communications — Trap Enable Mode.”](#)

The value used by the breakpoints generation logic is the bit wise OR of the software trap enable bits, (the bits written using the `mtspr`) and the development port trap enable bits (the bits serially shifted using the development port).

All bits, the software trap enable bits and the development port trap enable bits, can be read from `ICTRL` and the `LCTRL2` using `mfscr`. For the exact bits placement refer to [Section 23.6.10, “L-Bus Support Control Register 2”](#) and to [Section 23.6.10, “L-Bus Support Control Register 2.”](#)

## 23.3 Development System Interface

When debugging an existing system, it is sometimes desirable to be able to do so without the need to insert any changes in the existing system. In some cases it is not desired, or even impossible, to add load to the lines connected to the existing system. The development system interface of the CPU supports such a configuration.

The development system interface of the CPU uses a dedicated serial port (the development port) and, therefore, does not need any of the regular system interfaces. Controlling the activity of the system from the development port is done when the CPU is in the debug mode. The development port is a relatively

economical interface (three pins) that allows the development system to operate in a lower frequency than the frequency of the CPU. Note that it is also possible to debug the CPU using monitor debugger software, for more information refer to [Section 23.5, “Software Monitor Debugger Support.”](#)

Debug mode is a state where the CPU fetches all instructions from the development port. In addition, when in debug mode, data can be read from the development port and written to the development port. This allows memory and registers to be read and modified by a development tool (emulator) connected to the development port.

For protection purposes, two possible working modes are defined: debug mode enable and debug mode disable. These working modes are selected only during reset. For more information refer to [Section 23.3.1.1, “Debug Mode Enable vs. Debug Mode Disable.”](#)

The user can work in debug mode starting from reset or the CPU can be programmed to enter debug mode as a result of a predefined list of events. These events include all possible interrupts and exceptions in the CPU system, including the internal breakpoints, together with two levels of development port requests (masked and non-masked) and one peripheral breakpoint request that can be generated by any one of the peripherals of the system (including internal and external modules). Each event can be programmed either to be treated as a regular interrupt that causes the machine to branch to its interrupt vector, or to be treated as a special interrupt that causes debug mode entry.

When in debug mode an rfi instruction will return the machine to its regular work mode. The debugger tool should issue an isync instruction to the debug port prior to any other instructions when the CPU enters debug mode after running code.

The relationship between the debug mode logic to the rest of the CPU chip is shown in [Figure 23-5](#).

**Figure 23-5. Functional Diagram of MPC561/MPC563 Debug Mode Support**

The development port provides a full duplex serial interface for communications between the internal development support logic of the CPU and an external development tool. The development port can operate in two working modes: the trap enable mode and the debug mode.

The trap enable mode is used in order to shift into the CPU internal development support logic the following control signals:

1. Instruction trap enable bits, used for on the fly programming of the instruction breakpoint
2. Load/store trap enable bits, used for on the fly programming of the load/store breakpoint
3. Non-maskable breakpoint, used to assert the non-maskable external breakpoint
4. Maskable breakpoint, used to assert the maskable external breakpoint
5. VSYNC, used to assert and negate VSYNC

In debug mode the development port controls also the debug mode features of the CPU. For more information [Section 23.4, “Development Port.”](#)

### 23.3.1 Debug Mode Support

The debug mode of the CPU provides the development system with the following basic functions:

- Gives an ability to control the execution of the processor and maintain control on it under all circumstances. The development port is able to force the CPU to enter to the debug mode even when external interrupts are disabled.
- It is possible to enter debug mode immediately out of reset thus allowing debugging of a ROM-less system.
- It is possible to selectively define, using an enable register, the events that will cause the machine to enter into the debug mode.
- When in debug mode detect the reason upon which the machine entered debug mode by reading a cause register.
- Entering into the debug mode in all regular cases is restartable in the sense that it is possible to continue to run the regular program from the location where it entered the debug mode.
- When in debug mode all instructions are fetched from the development port but load/store accesses are performed on the real system memory.
- Data Register of the development port is accessed using mtspr and mfspr instructions via special load/store cycles. (This feature together with the last one enables easy memory dump & load).
- Upon entering debug mode, the processor gets into the privileged state ( $MSR[PR] = 0$ ). This allows execution of any instruction, and access to any storage location.
- An OR signal of all exception cause register (ECR) bits (ECR\_OR) enables the development port to detect pending events while already in debug mode. An example is the ability of the development port to detect a debug mode access to a non existing memory space.

Figure 23-6 illustrates the debug mode logic implemented in the CPU.

Figure 23-6. Debug Mode Logic

### 23.3.1.1 Debug Mode Enable vs. Debug Mode Disable

For protection purposes two possible working modes are defined: debug mode enable and debug mode disable. These working modes are selected only during reset. See [Figure 23-7](#) for BDM mode selection.

Debug mode is enabled by asserting DSCK during reset.

The debug interface is enabled by:

- holding JCOMP/ $\overline{\text{RSTI}}$  low while  $\overline{\text{HRESET}}$  is asserted and then entering BDM (DSCK=high at  $\overline{\text{HRESET}}$  negation)

or

- configuring READI to be disabled ( $\overline{\text{EVTI}}$ =high at  $\overline{\text{RSTI}}$  negation) and then entering BDM (DSCK=high at  $\overline{\text{HRESET}}$  negation)

The state of this pin is sampled three clocks before the negation of  $\overline{\text{SRESET}}$ .

### NOTE

Because  $\overline{\text{SRESET}}$  negation is done by an external pull up resistor any reference here to  $\overline{\text{SRESET}}$  negation time refers to the time the MPC561/MPC563 releases  $\overline{\text{SRESET}}$ . If the actual negation is slow due to a large resistor, set up time for the debug port signals should be set accordingly.

If the DSCK pin is sampled negated, debug mode is disabled until a subsequent reset when the DSCK pin is sampled in the asserted state. When debug mode is disabled the internal watchpoint/breakpoint hardware will still be operational and may be used by a software monitor program for debugging purposes.

When debug mode is disabled, all development support registers (see list in [Table 23-14](#)) are accessible to the supervisor code ( $\text{MSR}[\text{PR}] = 0$ ) and can be used by a monitor debugger software. However, the processor never enters debug mode and, therefore, the exception cause register (ECR) and the debug enable register (DER) are used only for asserting and negating the freeze signal. For more information on the software monitor debugger support refer to [Section 23.5, “Software Monitor Debugger Support.”](#)

When debug mode is enabled, all development support registers are accessible only when the CPU is in debug mode. Therefore, even supervisor code that may be still under debug cannot prevent the CPU from entering debug mode. The development system has full control of all development support features of the CPU through the development port. Refer to [Table 23-16](#).

Figure 23-7. BDM Mode Selection

### 23.3.1.2 Entering Debug Mode

Entering debug mode can be a result of a number of events. All events have a programmable enable bit to selectively decide which events result in debug mode entry and which in regular interrupt handling.

Entering debug mode is also possible immediately out of reset, thus allowing the debugging of even a ROM-less system. Using this feature is possible by special programming of the development port during reset. If the DSCK pin continues to be asserted following  $\overline{\text{SRESET}}$  negation (after enabling debug mode) the processor will take a breakpoint exception and go directly to debug mode instead of fetching the reset vector. To avoid entering debug mode following reset, the DSCK pin must be negated no later than seven clock cycles after  $\overline{\text{SRESET}}$  negates. In this case, the processor will jump to the reset vector and begin normal execution. When entering debug mode immediately after reset, bit 31 (development port interrupt) of the exception cause register (ECR) is set.

**Figure 23-8. Debug Mode Reset Configuration**

When debug mode is disabled all events result in regular interrupt handling.

The internal freeze signal is asserted whenever an enabled event occurs, regardless if debug mode is enabled or disabled. The internal freeze signal is connected to all relevant internal modules. These modules can be programmed to stop all operations in response to the assertion of the freeze signal. Refer to [Section 23.5.1, “Freeze Indication.”](#)

The freeze indication is negated when exiting debug mode. Refer to [Section 23.3.1.6, “Exiting Debug Mode.”](#)

The following list contains the events that can cause the CPU to enter debug mode. Each event results in debug mode entry if debug mode is enabled and the corresponding enable bit is set. The reset values of the enable bits allow, in most cases, the use of the debug mode features without the need to program the debug enable register (DER). For more information refer to [Section 23.6.13, “Development Port Data Register \(DPDR\).”](#)

- NMI exception as a result of the assertion of the IRQ0\_B pin. For more information refer to [Section 3.15.4.1, “System Reset Exception and NMI \(0x0100\).”](#)
- Check stop. Refer to [Section 23.3.1.3, “Check Stop State and Debug Mode,”](#) for more information.
- Machine check exception
- Implementation specific instruction protection error

- Implementation specific data protection error
- External interrupt, recognized when  $MSR[EE] = 1$
- Alignment interrupt
- Program interrupt
- Floating point unavailable exception
- Floating point assist exception
- Decrementer exception, recognized when  $MSR[EE] = 1$
- System call exception
- Trace, asserted when in single trace mode or when in branch trace mode (refer to [Section 3.15.4.11](#), “Trace Exception (0x0D00)”)
- Implementation dependent software emulation exception
- Instruction breakpoint, when breakpoints are masked (BRKNOMSK bit in the LCTRL2 is clear) recognized only when  $MSR[RI] = 1$ , when breakpoints are not masked (BRKNOMSK bit in the LCTRL2 is set) always recognized
- Load/store breakpoint, when breakpoints are masked (BRKNOMSK bit in the LCTRL2 is cleared) recognized only when  $MSR[RI] = 1$ , when breakpoints are not masked (BRKNOMSK bit in the LCTRL2 is set) always recognized
- Peripherals breakpoint, from the development port, internal and external modules. are recognized only when  $MSR[RI] = 1$ .
- Development port non-maskable interrupt, as a result of a debug station request. Useful in some catastrophic events like an endless loop when  $MSR[RI] = 0$ . As a result of this event the machine may enter a non-restartable state, for more information refer to [Section 3.13.4](#), “Exceptions.”

The processor enters into the debug mode state when at least one of the bits in the exception cause register (ECR) is set, the corresponding bit in the debug enable register (DER) is enabled and debug mode is enabled. When debug mode is enabled and an enabled event occurs, the processor waits until its pipeline is empty and then starts fetching the next instructions from the development port. For information on the exact value of machine status save/restore registers (SRR0 and SRR1) refer to [Section 3.13.4](#), “Exceptions.”

When the processor is in debug mode the freeze indication is asserted thus allowing any peripheral that is programmed to do so to stop. The fact that the CPU is in debug mode is also broadcast to the external world using the value b11 on the VFLS pins.

#### NOTE

The freeze signal can be asserted by software when debug mode is disabled.

The development port should read the value of the exception cause register (ECR) in order to get the cause of the debug mode entry. Reading the exception cause register (ECR) clears all its bits.

### 23.3.1.3 Check Stop State and Debug Mode

The CPU enters the check stop state if the machine check interrupt is disabled ( $MSR[ME] = 0$ ) and a machine check interrupt is detected. However, if a machine check interrupt is detected when  $MSR[ME] =$

0, debug mode is enabled and the check stop enable bit in the debug enable register (DER) is set, the CPU enters debug mode rather than the check stop state.

The different actions taken by the CPU when a machine check interrupt is detected are shown in the following table.

**Table 23-9. Check Stop State and Debug Mode**

| MSR[ME] | Debug Mode Enable | CHSTPE <sup>1</sup> | MCIE <sup>2</sup> | Action Performed by the CPU when Detecting a Machine Check Interrupt | Exception Cause Register (ECR) Value |
|---------|-------------------|---------------------|-------------------|----------------------------------------------------------------------|--------------------------------------|
| 0       | 0                 | X                   | X                 | Enter the check stop state                                           | 0x2000_0000                          |
| 1       | 0                 | X                   | X                 | Branch to the machine check interrupt                                | 0x1000_0000                          |
| 0       | 1                 | 0                   | X                 | Enter the check stop state                                           | 0x2000_0000                          |
| 0       | 1                 | 1                   | X                 | Enter Debug Mode                                                     | 0x2000_0000                          |
| 1       | 1                 | X                   | 0                 | Branch to the machine check interrupt                                | 0x1000_0000                          |
| 1       | 1                 | X                   | 1                 | Enter Debug Mode                                                     | 0x1000_0000                          |

<sup>1</sup> Check stop enable bit in the debug enable register (DER)

<sup>2</sup> Machine check interrupt enable bit in the debug enable register (DER)

#### 23.3.1.4 Saving Machine State upon Entering Debug Mode

If entering debug mode was as a result of any load/store type exception, and therefore the DAR (data address register) and DSISR (data storage interrupt status register) have some significant value, these two registers must be saved before any other operation is performed. Failing to save these registers may result in loss of their value in case of another load/store type exception inside the development software.

Since exceptions are treated differently when in debug mode (refer to [Section 23.3.1.5, “Running in Debug Mode”](#)), there is no need to save machine status save/restore zero register (SRR0) and machine status save/restore one register (SRR1).

#### 23.3.1.5 Running in Debug Mode

When running in debug mode all fetch cycles access the development port regardless of the actual address of the cycle. All load/store cycles access the real memory system according to the cycle’s address. The data register of the development port is mapped as a special control register therefore it is accessed using mtspr and mfspr instructions via special load/store cycles (refer to [Section 23.6.13, “Development Port Data Register \(DPDR\)”](#)).

Exceptions are treated differently when running in debug mode. When already in debug mode, upon recognition of an exception, the exception cause register (ECR) is updated according to the event that caused the exception, a special error indication (ecr\_or) is asserted for one clock cycle to report to the development port that an exception occurred and execution continues in debug mode without any change in SRR0 and SRR1. ECR\_OR is asserted before the next fetch occurs to allow the development system to detect the excepting instruction.

Not all exceptions are recognized when in debug mode. Breakpoints and watchpoints are not generated by the hardware when in debug mode (regardless of the value of MSR[RI]). Upon entering debug mode MSR[EE] is cleared by the hardware thus forcing the hardware to ignore external and decremented interrupts.

### WARNING

Setting the MSR[EE] bit while in debug mode, (by the debug software), is strictly forbidden. The reason for this restriction is that the external interrupt event is a level signal, and since the CPU only reports exceptions while in debug mode but do not treat them, the CPU does not clear the MSR[EE] bit and, therefore, this event, if enabled, is recognized again every clock cycle.

When the ecr\_or signal is asserted the development station should investigate the exception cause register (ECR) in order to find out the event that caused the exception.

Since the values in SRR0 and SRR1 do not change if an exception is recognized while already in debug mode, they only change once when entering debug mode, saving them when entering debug mode is not necessary.

#### 23.3.1.6 Exiting Debug Mode

The rfi instruction is used to exit from debug mode in order to return to the normal processor operation and to negate the freeze indication. The development system may monitor the freeze status to make sure the MPC561/MPC563 is out of debug mode. It is the responsibility of the software to read the exception cause register (ECR) before performing the rfi. Failing to do so will force the CPU to immediately re-enter to debug mode and to re-assert the freeze indication in case an asserted bit in the interrupt cause register (ECR) has a corresponding enable bit set in the debug enable register (DER).

## 23.4 Development Port

The development port provides a full duplex serial interface for communications between the internal development support logic including debug mode and an external development tool.

The relationship of the development support logic to the rest of the CPU chip is shown in [Figure 23-5](#). The development port support logic is shown as a separate block for clarity. It is implemented as part of the SIU module.

### 23.4.1 Development Port Pins

The following development port pin functions are provided:

1. Development serial clock (DSCK)
2. Development serial data in (DSDI)
3. Development serial data out (DSDO)

## 23.4.2 Development Serial Clock

The development serial clock (DSCK) is used to shift data into and out of the development port shift register. At the same time, the new most significant bit of the shift register is presented at the DSDO pin. In all further discussions references to the DSCK signal imply the internal synchronized value of the clock. The DSCK input must be driven either high or low at all times and not allowed to float. A typical target environment would pull this input low with a resistor.

The clock may be implemented as a free running clock or as gated clock. As discussed in section [Section 23.4.6.5, “Development Port Serial Communications — Trap Enable Mode”](#) and section [Section 23.4.6.8, “Development Port Serial Communications — Debug Mode,”](#) the shifting of data is controlled by ready and start signals so the clock does not need to be gated with the serial transmissions.

The DSCK pin is also used at reset to enable debug mode and immediately following reset to optionally cause immediate entry into debug mode following reset.

## 23.4.3 Development Serial Data In

Data to be transferred into the development port shift register is presented at the development serial data in (DSDI) pin by external logic. To be sure that the correct value is used internally. When driven asynchronous (synchronous) with the system clock, the data presented to DSDI must be stable a setup time before the rising edge of DSCK (CLKOUT) and a hold time after the rising edge of DSCK (CLKOUT).

The DSDI pin is also used at reset to control the overall chip configuration mode and to determine the development port clock mode. See section [Section 23.4.6.4, “Development Port Serial Communications — Clock Mode Selection”](#) for more information.

## 23.4.4 Development Serial Data Out

The debug mode logic shifts data out of the development port shift register using the development serial data out (DSDO) pin. All transitions on DSDO are synchronous with DSCK or CLKOUT depending on the clock mode. Data will be valid a setup time before the rising edge of the clock and will remain valid a hold time after the rising edge of the clock.

Refer to [Table 23-12](#) for DSDO data meaning.

## 23.4.5 Freeze Signal

The freeze indication means that the processor is in debug mode (i.e., normal processor execution of user code is frozen). On the MPC561/MPC563, the freeze state can be indicated by three different pins. The FRZ signal is generated synchronously with the system clock. This indication may be used to halt any off-chip device while in debug mode as well as a handshake means between the debug tool and the debug port. The internal freeze status can also be monitored through status in the data shifted out of the debug port.

### 23.4.5.1 SGPIO6/FRZ/ $\overline{\text{PTR}}$ Signal

The SGPIO6/FRZ/ $\overline{\text{PTR}}$  signal powers up as the  $\overline{\text{PTR}}$  function and its function is controlled by the GPC bits in the SIUMCR.

### 23.4.5.2 IWP[0:1]/VFLS[0:1] Signals

The power-up state of IWP[0:1]/VFLS[0:1] is controlled by setting the SIUMCR[DBGC]; see [Table 6-8](#). They can also be set via the reset configuration word (See [Section 7.5.2, “Hard Reset Configuration Word \(RCW\)”](#)). The FRZ state is indicated by the value 0b11 on the VFLS[0:1] signals.

### 23.4.5.3 VFLS[0:1]/MPIO32B[3:4] Signals

The VFLS[0:1]/MPIO32B[3:4] signals power up as the MPIO32B[3:4] function and their function can be changed via the VFLS bit in the MIOS14TPCR register. The FRZ state is indicated by the value 0b11 on the VFLS[0:1] signals.

## 23.4.6 Development Port Registers

The development port consists logically of the three registers: development port instruction register (DPIR), development port data register (DPDR), and trap enable control register (TECR). These registers are physically implemented as two registers, development port shift register and trap enable control register. The development port shift register acts as both the DPIR and DPDR depending on the operation being performed. It is also used as a temporary holding register for data to be stored into the TECR. These registers are discussed below in more detail.

### 23.4.6.1 Development Port Shift Register

The development port shift register is a 35-bit shift register. Instructions and data are shifted into it serially from DSDI using DSCK (or CLKOUT depending on the debug port clock mode, refer to [Section 23.4.6.4, “Development Port Serial Communications — Clock Mode Selection”](#)) as the shift clock. These instructions or data are then transferred in parallel to the CPU, the trap enable control register (TECR). When the processor enters debug mode it fetches instructions from the DPIR which causes an access to the development port shift register. These instructions are serially loaded into the shift register from DSDI using DSCK (or CLKOUT) as the shift clock. In a similar way, data is transferred to the CPU by moving it into the shift register which the processor reads as the result of executing a “move from special purpose register DPDR” instruction. Data is also parallel-loaded into the development port shift register from the CPU by executing a “move to special purpose register DPDR” instruction. It is then shifted out serially to DSDO using DSCK (or CLKOUT) as the shift clock.

### 23.4.6.2 Trap Enable Control Register

The trap enable control register is a 9-bit register that is loaded from the development port shift register. The contents of the control register are used to drive the six trap enable signals, the two breakpoint signals, and the VSYNC signal to the CPU. The “transfer data to trap enable control register” commands will cause the appropriate bits to be transferred to the control register.

The trap enable control register is not accessed by the CPU, but instead supplies signals to the CPU. The trap enable bits, VSYNC bit, and the breakpoint bits of this register are loaded from the development port shift register as the result of trap enable mode transmissions. The trap enable bits are reflected in ICTRL and LCTRL2 special registers. See [Section 23.6.10, “L-Bus Support Control Register 2”](#) and [Section 23.6.10, “L-Bus Support Control Register 2.”](#)

### 23.4.6.3 Development Port Registers Decode

The development port shift register is selected when the CPU accesses DPIR or DPDR. Accesses to these two special purpose registers occur in debug mode and appear on the internal bus as an address and the assertion of an address attribute signal indicating that a special purpose register is being accessed. The DPIR register is read by the CPU to fetch all instructions when in debug mode and the DPDR register is read and written to transfer data between the CPU and external development tools. The DPIR and DPDR are pseudo registers. Decoding either of these registers will cause the development port shift register to be accessed. The debug mode logic knows whether the CPU is fetching instructions or reading or writing data. If what the CPU is expecting and what the register receives from the serial port do not match (instruction instead of data) the mismatch is used to signal a sequence error to the external development tool.

### 23.4.6.4 Development Port Serial Communications — Clock Mode Selection

All of the serial transmissions are clock transmissions and are therefore synchronous communications. However, the transmission clock may be either synchronous or asynchronous with the system clock (CLKOUT). The development port allows the selection of two methods for clocking the serial transmissions. The first method allows the transmission to occur without being externally synchronized with CLKOUT, in this mode a serial clock DSCK must be supplied to the MPC561/MPC563. The other communication method requires a data to be externally synchronized with CLKOUT.

The first clock mode is called “asynchronous clock” since the input clock (DSCK) is asynchronous with CLKOUT. To be sure that data on DSDI is sampled correctly, transitions on DSDI must occur a setup time ahead and a hold time after the rising edge of DSCK. This clock mode allows communications with the port from a development tool which does not have access to the CLKOUT signal or where the CLKOUT signal has been delayed or skewed. Refer to the timing diagram in [Figure 23-9](#).

The second clock mode is called “synchronous self clock”. It does not require an input clock. Instead the port is timed by the system clock. The DSDI input is required to meet setup and hold time requirements with respect to CLKOUT rising edge. The data rate for this mode is always the same as the system clock. Refer to the timing diagram in [Figure 23-10](#).

The selection of clock or self clock mode is made at reset. The state of the DSDI input is latched eight clocks after  $\overline{\text{SRESET}}$  negates. If it is latched low, asynchronous clock mode is enabled. If it is latched high then synchronous self clock mode is enabled.

Since DSDI is used to select the development port clocking scheme, it is necessary to prevent any transitions on DSDI during this time from being recognized as the start of a serial transmission. The port will not begin scanning for the start bit of a serial transmission until 16 clocks after the negation of  $\overline{\text{SRESET}}$ . If DSDI is asserted 16 clocks after  $\overline{\text{SRESET}}$  negation, the port will wait until DSDI is negated to begin scanning for the start bit.

**Note:** DCLK and DSDI transitions are not required to be synchronous with CLKOUT.

**Figure 23-9. Asynchronous Clock Serial Communications**

**Figure 23-10. Synchronous Self Clock Serial Communication**

**Figure 23-11. Enabling Clock Mode Following Reset**

#### 23.4.6.5 Development Port Serial Communications — Trap Enable Mode

When not in debug mode the development port starts communications by setting DSDO (the MSB of the 35-bit development port shift register) low to indicate that all activity related to the previous transmission are complete and that a new transmission may begin. The start of a serial transmission from an external development tool to the development port is signaled by a start bit. A mode bit in the transmission defines the transmission as either a trap enable mode transmission or a debug mode transmission. If the mode bit is set the transmission will only be 10 bits long and only seven data bits will be shifted into the shift register. These seven bits will be latched into the TECR. A control bit determines whether the data is latched into the trap enable and VSYNC bits of the TECR or into the breakpoints bits of the TECR.

#### 23.4.6.6 Serial Data into Development Port — Trap Enable Mode

The development port shift register is 35 bits wide but trap enable mode transmissions only use the start/ready bit, a mode/status bit, a control/status bit, and the seven least significant data bits. The encoding of data shifted into the development port shift register (through the DSDI pin) is shown in [Table 23-10](#) and [Table 23-11](#) below:

**Table 23-10. Trap Enable Data Shifted into Development Port Shift Register**

| Start | Mode | Control | 1st                       | 2nd | 3rd | 4th | 1st        | 2nd | VSYNC                                         | Function |
|-------|------|---------|---------------------------|-----|-----|-----|------------|-----|-----------------------------------------------|----------|
|       |      |         | ----- Instruction -----   |     |     |     | -- Data -- |     |                                               |          |
|       |      |         | Watchpoint Trap Enables   |     |     |     |            |     |                                               |          |
| 1     | 1    | 0       | 0 = disabled; 1 = enabled |     |     |     |            |     | Transfer Data to Trap Enable Control Register |          |

**Table 23-11. Debug Port Command Shifted into Development Port Shift Register**

| Start | Mode | Control | Extended Opcode |   | Major Opcode   | Function                        |
|-------|------|---------|-----------------|---|----------------|---------------------------------|
| 1     | 1    | 1       | x               | x | 00000          | NOP                             |
|       |      |         |                 |   | 00001          | Hard Reset request              |
|       |      |         |                 |   | 00010          | Soft Reset request              |
|       |      |         | 0               | x | 00011          | Reserved                        |
|       |      |         | 1               | 0 | 00011          | End Download procedure          |
|       |      |         | 1               | 1 | 00011          | Start Download procedure        |
|       |      |         | x               | x | 00100... 11110 | Reserved                        |
|       |      |         | x               | 0 | 11111          | Negate Maskable breakpoint.     |
|       |      |         | x               | 1 | 11111          | Assert Maskable breakpoint.     |
|       |      |         | 0               | x | 11111          | Negate Non Maskable breakpoint. |
|       |      |         | 1               | x | 11111          | Assert Non Maskable breakpoint. |

The watchpoint trap enables and VSYNC functions are described in section [Section 23.2, “Watchpoints and Breakpoints Support”](#) and section [Section 23.1, “Program Flow Tracking.”](#)

The debug port command function allows the development tool to either assert or negate breakpoint requests, reset the processor, activate or deactivate the fast down-load procedure.

#### 23.4.6.7 Serial Data Out of Development Port — Trap Enable Mode

In trap enable mode the only response out of the development port is “sequencing error.”

Data that can come out of the development port is shown in [Table 23-12](#). “Valid data from CPU” and “CPU interrupt” status cannot occur in trap enable mode.

**Table 23-12. Status / Data Shifted Out of Development Port Shift Register**

| Ready | Status [0:1] |   | Data                          |                                                      |                                                 | Function            |
|-------|--------------|---|-------------------------------|------------------------------------------------------|-------------------------------------------------|---------------------|
|       |              |   | Bit 0                         | Bit 1                                                | Bits 2:31 or 2:6 —<br>(Depending on Input Mode) |                     |
| (0)   | 0            | 0 | Data                          |                                                      |                                                 | Valid Data from CPU |
| (0)   | 0            | 1 | Freeze<br>status <sup>1</sup> | Download<br>Procedure<br>in<br>progress <sup>2</sup> | 1's                                             | Sequencing Error    |
| (0)   | 1            | 0 |                               |                                                      | 1's                                             | CPU Interrupt       |
| (0)   | 1            | 1 |                               |                                                      | 1's                                             | Null                |

<sup>1</sup> The "Freeze" status is set to (1) when the CPU is in debug mode and to (0) otherwise.

<sup>2</sup> The "Download Procedure in progress" status is asserted (0) when Debug port in the Download procedure and is negated (1) otherwise.

When not in debug mode the sequencing error encoding indicates that the transmission from the external development tool was a debug mode transmission. When a sequencing error occurs the development port will ignore the data shifted in while the sequencing error was shifting out. It will be treated as a NOP function.

Finally, the null output encoding is used to indicate that the previous transmission did not have any associated errors.

When not in debug mode, ready will be asserted at the end of each transmission. If debug mode is not enabled and transmission errors can be guaranteed not to occur, the status output is not needed.

### 23.4.6.8 Development Port Serial Communications — Debug Mode

When in debug mode the development port starts communications by setting DSDO low to indicate that the CPU is trying to read an instruction from DPIR or data from DPDR. When the CPU writes data to the port to be shifted out the ready bit is not set. The port waits for the CPU to read the next instruction before asserting ready. This allows duplex operation of the serial port while allowing the port to control all transmissions from the external development tool. After detecting this ready status the external development tool begins the transmission to the development port with a start bit (logic high) on the DSDI pin.

### 23.4.6.9 Serial Data Into Development Port

In debug mode the 35 bits of the development port shift register are interpreted as a start/ready bit, a mode/status bit, a control/status bit, and 32 bits of data. All instructions and data for the CPU are transmitted with the mode bit cleared indicating a 32-bit data field. The encoding of data shifted into the development port shift register (through the DSDI pin) is shown below in [Table 23-13](#).

**Table 23-13. Debug Instructions / Data Shifted into Development Port Shift Register**

| Start | Mode | Control | Instruction / Data (32 Bits) |                | Function                                      |
|-------|------|---------|------------------------------|----------------|-----------------------------------------------|
|       |      |         | Bits 0:6                     | Bits 7:31      |                                               |
| 1     | 0    | 0       | CPU Instruction              |                | Transfer Instruction to CPU                   |
| 1     | 0    | 1       | CPU Data                     |                | Transfer Data to CPU                          |
| 1     | 1    | 0       | Trap enable <sup>1</sup>     | Does not exist | Transfer data to Trap Enable Control Register |
| 1     | 1    | 1       | 0011111                      | Does not exist | Negate breakpoint requests to the CPU.        |
| 1     | 1    | 1       | 0                            | Does not exist | NOP                                           |

<sup>1</sup> Refer to [Table 23-10](#)

Data values in the last two functions other than those specified are reserved.

All transmissions from the debug port on DSDO begin with a “0” or “ready” bit. This indicates that the CPU is trying to read an instruction or data from the port. The external development tool must wait until it sees DSDO go low to begin sending the next transmission.

The control bit differentiates between instructions and data and allows the development port to detect that an instruction was entered when the CPU was expecting data and vice versa. If this occurs a sequence error indication is shifted out in the next serial transmission.

The trap enable function allows the development tool to transfer data to the trap enable control register.

The debug port command function allows the development tool to either negate breakpoint requests, reset the processor, activate or deactivate the fast down load procedure.

The NOP function provides a null operation for use when there is data or a response to be shifted out of the data register and the appropriate next instruction or command will be determined by the value of the response or data shifted out.

### 23.4.6.10 Serial Data Out of Development Port

The encoding of data shifted out of the development port shift register in debug mode (through the DSDO pin) is the same as for trap enable mode and is shown in [Table 23-12](#).

Valid data encoding is used when data has been transferred from the CPU to the development port shift register. This is the result of an instruction to move the contents of a general purpose register to the debug port data register (DPDR). The valid data encoding has the highest priority of all status outputs and will be reported even if an interrupt occurs at the same time. Since it is not possible for a sequencing error to occur and also have valid data there is no priority conflict with the sequencing error status. Also, any interrupt that is recognized at the same time that there is valid data is not related to the execution of an

instruction. Therefore, a valid data status will be output and the interrupt status will be saved for the next transmission.

The sequencing error encoding indicates that the inputs from the external development tool are not what the development port and/or the CPU was expecting. Two cases could cause this error:

1. The processor was trying to read instructions and there was data shifted into the development port, or
2. The processor was trying to read data and there was instruction shifted into the development port. The port will terminate the read cycle with a bus error.

This bus error will cause the CPU to signal that an interrupt (exception) occurred. Since a status of sequencing error has a higher priority than exception, the port will report the sequencing error first, and the CPU interrupt on the next transmission. The development port will ignore the command, instruction, or data shifted in while the sequencing error or CPU interrupt is shifted out. The next transmission after all error status is reported to the port should be a new instruction, trap enable or command (possibly the one that was in progress when the sequencing error occurred).

The interrupt-occurred encoding is used to indicate that the CPU encountered an interrupt during the execution of the previous instruction in debug mode. Interrupts may occur as the result of instruction execution (such as unimplemented opcode or arithmetic error), because of a memory access fault, or from an unmasked external interrupt. When an interrupt occurs the development port will ignore the command, instruction, or data shifted in while the interrupt encoding was shifting out. The next transmission to the port should be a new instruction, trap enable or debug port command.

Finally, the null encoding is used to indicate that no data has been transferred from the CPU to the development port shift register.

### 23.4.6.11 Fast Download Procedure

The download procedure is used to download a block of data from the debug tool into system memory. This procedure can be accomplished by repeating the following sequence of transactions from the development tool to the debug port for the number of data words to be down loaded:

```
INIT:    Save RX, RY
        RY <- Memory Block address- 4

        ...

repeat:  mfspr    RX, DPDR
        DATA word to be moved to memory
        stwu     RX, 0x4(RY)
until here

        ...

        Restore RX,RY
```

**Figure 23-12. Download Procedure Code Example**

For large blocks of data this sequence may take significant time to complete. The “fast download procedure” of the debug port may be used to reduce this time. This time reduction is achieved by eliminating the need to transfer the instructions in the loop to the debug port. The only transactions needed are those required to transfer the data to be placed in system memory. [Figure 23-13](#) and [Figure 23-14](#) illustrate the time benefit of the “fast download procedure”.

**Figure 23-13. Slow Download Procedure Loop**

**Figure 23-14. Fast Download Procedure Loop**

The sequence of the instructions used in the “fast download procedure” is the one illustrated in [Figure 23-12](#) with  $RX = r31$  and  $RY = r30$ . This sequence is repeated infinitely until the “end download procedure” command is issued to the debug port.

Note that, the internal general purpose register 31 is used for temporary storage data value. Before beginning the “fast download procedure” by the “start download procedure command”, The value of the first memory block address,  $-4$ , must be written to the general purpose register 30.

To end a download procedure, an “end download procedure” command should be issued to the debug port, and then, additional DATA transaction should be sent by the development tool. This data word will NOT be placed into the system memory, but it is needed to stop the procedure gracefully.

## 23.5 Software Monitor Debugger Support

When in debug mode disable, a software monitor debugger can make use of all of the development support features defined in the CPU. When debug mode is disabled all events result in regular interrupt handling, i.e. the processor resumes execution in the corresponding interrupt handler. The exception cause register (ECR) and the debug enable register (DER) only influence the assertion and negation of the freeze signal.

### 23.5.1 Freeze Indication

The internal freeze signal is connected to all relevant internal modules. These modules can be programmed to stop all operations in response to the assertion of the freeze signal. In order to enable a software monitor debugger to broadcast the fact that the debug software is now executed, it is possible to assert and negate the internal freeze signal also when debug mode is disabled.

The assertion and negation of the freeze signal when in debug mode disable is controlled by the exception cause register (ECR) and the debug enable register (DER) as described in [Figure 23-6](#). In order to assert the freeze signal the software needs to program the relevant bits in the debug enable register (DER). In order to negate the freeze line the software needs to read the exception cause register (ECR) in order to clear it and perform an rfi instruction.

If the exception cause register (ECR) is not cleared before the rfi is performed the freeze signal is not negated. Therefore it is possible to nest inside a software monitor debugger without affecting the value of the freeze line although rfi may be performed a few times. Only before the last rfi the software needs to clear the exception cause register (ECR).

The above mechanism enables the software to accurately control the assertion and the negation of the freeze signal.

## 23.6 Development Support Registers

[Table 23-14](#) lists the registers used for development support in SPR number order, and the register sections, [Section 23.6.2, “Comparator A–D Value Registers \(CMPA–CMPD\)”](#) through [Section 23.6.13, “Development Port Data Register \(DPDR\)”](#) follow the same SPR order. The registers are accessed with the mtspr and mfspr instructions.

**Table 23-14. Development Support Programming Model**

| SPR Number<br>(Decimal) | Name                                                                                                              |
|-------------------------|-------------------------------------------------------------------------------------------------------------------|
| 144                     | Comparator A Value Register (CMPA)<br>See <a href="#">Table 23-17</a> for bit descriptions.                       |

## 23.6.1 Register Protection

[Table 23-15](#) and [Table 23-16](#) summarize protection features of development support registers during read and write accesses, respectively.

**Table 23-15. Development Support Registers Read Access Protection**

| MSR[PR] | Debug Mode Enable | In Debug Mode | Result                                                                                         |
|---------|-------------------|---------------|------------------------------------------------------------------------------------------------|
| 0       | 0                 | X             | Read is performed.<br>ECR is cleared when read.<br>Reading DPDR yields indeterminate data.     |
| 0       | 1                 | 0             | Read is performed.<br>ECR is not cleared when read.<br>Reading DPDR yields indeterminate data. |
| 0       | 1                 | 1             | Read is performed.<br>ECR is cleared when read.                                                |
| 1       | X                 | X             | Program exception is generated.<br>Read is not performed.<br>ECR is not cleared when read.     |

**Table 23-16. Development Support Registers Write Access Protection**

| MSR[PR] | Debug Mode Enable | In Debug Mode | Result                                                                         |
|---------|-------------------|---------------|--------------------------------------------------------------------------------|
| 0       | 0                 | X             | Write is performed.<br>Write to ECR is ignored.<br>Writing to DPDR is ignored. |
| 0       | 1                 | 0             | Write is not performed.<br>Writing to DPDR is ignored.                         |
| 0       | 1                 | 1             | Write is performed.<br>Write to ECR is ignored.                                |
| 1       | X                 | X             | Write is not performed.<br>Program exception is generated.                     |

### 23.6.2 Comparator A–D Value Registers (CMPA–CMPD)

**Figure 23-15. Comparator A–D Value Register (CMPA–CMPD)**
**Table 23-17. CMPA-CMPD Bit Descriptions**

| Bits | Mnemonic | Description                 |
|------|----------|-----------------------------|
| 0:31 | CMPA-D   | Address bits to be compared |

**Note:** These registers are unaffected by reset.

### 23.6.3 Exception Cause Register (ECR)

The ECR indicates the cause of entry into debug mode. All bits are set by the hardware and cleared when the register is read when debug mode is disabled, or if the processor is in debug mode. Attempts to write to this register are ignored. When the hardware sets a bit in this register, debug mode is entered only if debug mode is enabled and the corresponding mask bit in the DER is set.

All bits are cleared to zero following reset.

**Figure 23-16. Exception Cause Register (ECR)**

**Table 23-18. ECR Bit Descriptions**

| Bits  | Name   | Description                                                                                                                                                                                                           |
|-------|--------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0     | —      | Reserved                                                                                                                                                                                                              |
| 1     | RST    | Reset interrupt bit. This bit is set when the system reset pin is asserted.                                                                                                                                           |
| 2     | CHSTP  | Checkstop bit. Set when the processor enters checkstop state.                                                                                                                                                         |
| 3     | MCE    | Machine check interrupt bit. Set when a machine check exception (other than one caused by a data storage or instruction storage error) is asserted.                                                                   |
| 4:5   | —      | Reserved                                                                                                                                                                                                              |
| 6     | EXTI   | External interrupt bit. Set when the external interrupt is asserted.                                                                                                                                                  |
| 7     | ALE    | Alignment exception bit. Set when the alignment exception is asserted.                                                                                                                                                |
| 8     | PRE    | Program exception bit. Set when the program exception is asserted.                                                                                                                                                    |
| 9     | FPUVE  | Floating point unavailable exception bit. Set when the program exception is asserted.                                                                                                                                 |
| 10    | DECE   | Decrementer exception bit. Set when the decremter exception is asserted.                                                                                                                                              |
| 11:12 | —      | Reserved                                                                                                                                                                                                              |
| 13    | SYSE   | System call exception bit. Set when the system call exception is asserted.                                                                                                                                            |
| 14    | TR     | Trace exception bit. Set when in single-step mode or when in branch trace mode.                                                                                                                                       |
| 15    | FPASE  | Floating point assist exception bit. Set when the floating point assist exception occurs.                                                                                                                             |

| 21    | DTLBER | Implementation specific data protection error<br>This bit is set as a result of an data protection error. Results in debug mode entry if debug mode is enabled and the corresponding enable bit is set.               |

**Table 23-18. ECR Bit Descriptions (continued)**

| Bits  | Name | Description                                                                                                                                                                                                                                                                                                                                                            |
|-------|------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 22:27 | —    | Reserved                                                                                                                                                                                                                                                                                                                                                               |
| 28    | LBRK | L-bus breakpoint exception bit. This bit is set as a result of the assertion of a load/store breakpoint. Results in debug mode entry if debug mode is enabled and the corresponding enable bit is set.                                                                                                                                                                 |
| 29    | IBRK | I-bus breakpoint exception bit. This bit is set as a result of the assertion of an Instruction breakpoint. Results in debug mode entry if debug mode is enabled and the corresponding enable bit is set.                                                                                                                                                               |
| 30    | EBRK | External breakpoint exception bit. Set when an external breakpoint is asserted (by an on-chip IMB or L-bus module, or by an external device or development system through the development port). This bit is set as a result of the assertion of an external breakpoint. Results in debug mode entry if debug mode is enabled and the corresponding enable bit is set. |
| 31    | DPI  | Development port interrupt bit. Set by the development port as a result of a debug station non-maskable request or when debug mode is entered immediately out of reset.                                                                                                                                                                                                |

### 23.6.4 Debug Enable Register (DER)

This register enables selectively masking the events that may cause the processor to enter into debug mode.

| 31    | SLW1EN   | Software trap enable selection of the 2nd L-bus watchpoint<br>0 trap disabled (reset value)<br>1 trap enabled                                                                       |

**Note:** LCTRL2 is cleared following reset.

For each watchpoint, three control register fields (LWxIA, LWxLA, LWxLD) must be programmed. For a watchpoint to be asserted, all three conditions must be detected.

## 23.6.11 I-Bus Support Control Register (ICTRL)

**Figure 23-24. I-Bus Support Control Register (ICTRL)**

<sup>1</sup> Changing the instruction show cycle programming starts to take effect only from the second instruction after the actual mtspr to ICTRL.

If the processor aborts a fetch of the target of a direct branch (due to an exception), the target is not always visible on the external pins. Program trace is not affected by this phenomenon.

**Table 23-26. ICTRL Bit Descriptions**

| Bits  | Mnemonic | Description                      | Function                                                                                                                                                                                                         |                                                                                                           |

### 23.6.13 Development Port Data Register (DPDR)

This 32-bit special purpose register physically resides in the development port logic. It is used for data interchange between the core and the development system. An access to this register is initiated using mtspr and mfspr (SPR 630) and implemented using a special bus cycle on the internal bus.

## Chapter 24

# READI Module

The READI module provides real-time development capabilities for RCPU-based MCUs in compliance with the Nexus IEEE-ISTO 5001-1999. This module provides development support capabilities for MCUs in single chip mode, without requiring address and data signals for internal visibility. The development features supported are program trace, data trace, watchpoint trace, ownership trace, run-time access to the MCU's internal memory map, and access to RCPU internal registers during halt, via the auxiliary port.

The auxiliary port, along with RCPU development features (such as background debug mode and watchpoints) supports all software and hardware development in single chip mode. The auxiliary port, along with (on-chip) calibration RAM, allows calibration variable acquisition and calibration constant tuning in single chip mode, for automotive powertrain development systems.

### NOTE

In this section the bit numbering in the register definitions of tool mapped registers follows the Nexus IEEE-ISTO 5001 - 1999 bit numbering convention of MSB = bit 31 and LSB = bit 0, unlike the MPC500 standard (MSB = bit 0 and LSB = bit 31). The bit description tables list the bit numbering and Nexus bit numbering.

## 24.1 Features Summary

The READI module is compliant with Class 3 of the IEEE-ISTO 5001-1999. The following features are implemented:

- Program trace via branch trace messaging (BTM). Branch trace messaging displays program flow discontinuities (direct and indirect branches, exceptions etc.), allowing the development tool to interpolate what transpires between the discontinuities. Thus static code may be traced.
- Data trace via data write messaging (DWM) and data read messaging (DRM). This provides the capability for the development tool to trace reads and/or writes to (selected) internal memory resources. Data trace also allows for calibration variable acquisition in automotive powertrain development systems.
  - Two data trace windows with programmable address range and access attributes. Data trace windowing reduces the requirements on the auxiliary port bandwidth by constraining the number of trace locations.
- Ownership trace via ownership trace messaging (OTM). OTM facilitates ownership trace by providing visibility of which process ID or operating system task is activated. An ownership trace message is transmitted to indicate when a new process/task is activated, allowing development tools to trace process/task flow.

- Run-time access to on-chip memory map and MPC500 special purpose registers (SPRs) via the READI read/write access protocol. This feature supports accesses for runtime internal visibility, calibration constant acquisition and tuning, and external rapid prototyping for powertrain automotive development systems.
- Watchpoint messaging via the auxiliary port
- Nine or 16 full-duplex auxiliary signal interface for medium and high visibility throughput
  - One of two modes selected during reset: full port mode (FPM) and reduced port mode (RPM).
    - FPM comprises 16 signals and RPM comprises nine signals
  - Auxiliary output port
    - One MCKO (message clock out) signal
    - Two or eight MDO (message data out) signals
    - One  $\overline{\text{MSEO}}$  (message start/end out) signal
  - Auxiliary input port
    - One  $\overline{\text{MCKI}}$  (message clock in) signal
    - One or two MDI (message data in) signals
    - One  $\overline{\text{MSEI}}$  (message start/end in) signal
    - One  $\overline{\text{EVTI}}$  (event in) signal
    - One  $\overline{\text{RSTI}}$  (reset in) signal
- All features configurable and controllable via the auxiliary port
- Security features for production environment
- Support of existing RCPU development access protocol via the auxiliary port
- READI module can be reset independent of system reset
- Parametrics:
  - Two bits are downloaded per clock in full port mode. For example, with input clock running at 28 MHz, this translates to a download rate of 56 Mbits/s.
  - One bit is downloaded per clock in reduced port mode. For example, with input clock running at 28 MHz, this translates to a download rate of 28 Mbits/s.
  - Eight bits are uploaded per clock in full port mode. For example, with system clock running at 56 MHz, this translates to a upload rate of 448 Mbits/s.
  - Two bits are uploaded per clock in reduced port mode. For example, with system clock running at 56 MHz, this translates to a upload rate of 112 Mbits/s.

### 24.1.1 Functional Block Diagram

The functional block diagram of the READI module is shown in [Figure 24-1](#).

Figure 24-1. READI Functional Block Diagram

## 24.2 Modes of Operation

The various operating modes of the READI module are:

1. Reset
2. Secure
3. Normal
4. Disabled

### 24.2.1 Reset Configuration

The READI reset configuration is explained in [Section 24.7.6, “READI Reset Configuration.”](#)

## 24.2.2 Security

Security is provided via the UC3F censorship mechanism. If a UC3F array is in censored mode, reads or writes to the UC3F will not be allowed (RCPU will not be able to fetch instructions from the UC3F) once any of the following cases are detected:

- Program trace and/or data trace are enabled
- Read/write access is attempted (can be to any address location)
- RCPU development access is enabled.

## 24.2.3 Normal

Normal operation of the READI module allows for development support features to be available. These features include control of the device, access to registers, and the ability to perform data or instruction trace.

## 24.2.4 Disabled

If  $\overline{\text{EVTI}}$  is negated at negation of  $\overline{\text{RSTI}}$ , the READI module will be disabled. No trace output will be provided, and output auxiliary port will be three-stated. Any message sent by the tool is ignored.

## 24.3 Parametrics

With 32-deep message queues, throughput numbers were calculated for the following benchmark codes [assuming full port mode]:

- For an example benchmark which had 10.9% direct branches, 2.5% indirect branches, 10.4% data writes, and 19.3% data reads, approximately 20% of total data trace accesses will be traced.
- For another example benchmark which had 9.8% direct branches, 2.8% indirect branches, 6.6% data writes, and 18.3% data reads, approximately 27% of total data trace accesses will be traced.

### NOTE

The queue is only 16 messages deep on revisions prior to Rev. D of the MPC561 and is 16 deep in Rev. B and earlier versions of the MPC563.

For reduced port mode, the data trace feature should not be used, or used sparingly, so as not to cause queue overruns.

## 24.4 Messages

The READI module implements messaging via the auxiliary port according to the IEEE-ISTO 5001 - 1999. Messaging will be implemented via transfer codes (TCODEs) on the auxiliary port. The TCODE number for the message identifies the transfer format (the number and/or size of packets to be transferred) and the purpose of each packet.

Public messages outlined in [Table 24-1](#) are supported by READI.

**Table 24-1. Public Messages**

| TCODE Number | Message Name                                                                                                                                                                                        |
|--------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1            | Device ID. Refer to <a href="#">Section 24.6.1.3, "Device ID Register (DID)."</a>                                                                                                                   |
| 2            | Ownership Trace Message. Refer to <a href="#">Section 24.13.1, "Ownership Trace Messaging."</a>                                                                                                     |
| 3            | Program Trace — Direct Branch Message. Refer to <a href="#">Section 24.8.2.1, "Direct Branch Messages."</a>                                                                                         |
| 4            | Program Trace — Indirect Branch Message. Refer to <a href="#">Section 24.8.2.2, "Indirect Branch Messages."</a>                                                                                     |
| 5            | Data Trace — Data Write Message. Refer to <a href="#">Section 24.9.2.1, "Data Write Message."</a>                                                                                                   |
| 6            | Data Trace — Data Read Message. Refer to <a href="#">Section 24.9.2.2, "Data Read Message."</a>                                                                                                     |
| 8            | Error Message. Refer to <a href="#">Table 24-20</a> .                                                                                                                                               |
| 10 (0x0A)    | Program Trace Correction. Refer to <a href="#">Section 24.8.2.3, "Correction Messages."</a>                                                                                                         |
| 11 (0x0B)    | Program Trace — Direct Branch Synchronization Message. Refer to <a href="#">Section 24.8.2.4.1, "Direct Branch Synchronization Message."</a>                                                        |
| 12 (0x0C)    | Program Trace — Indirect Branch Synchronization Message. Refer to <a href="#">Section 24.8.2.4.2, "Indirect Branch Synchronization Message."</a>                                                    |
| 13 (0x0D)    | Data Trace — Data Write Synchronization Message. Refer to <a href="#">Section 24.9.2.4, "Data Write Synchronization Message."</a>                                                                   |
| 14 (0x0E)    | Data Trace — Data Read Synchronization Message. Refer to <a href="#">Section 24.9.2.5, "Data Read Synchronization Messaging."</a>                                                                   |
| 15 (0x0F)    | Watchpoint Message. Refer to <a href="#">Section 24.12.1, "Watchpoint Messaging."</a>                                                                                                               |
| 16 (0x10)    | Auxiliary Access — Device Ready for Upload/Download Message. Refer to <a href="#">Section 24.6.2, "Accessing Memory-Mapped Locations Via the Auxiliary Port."</a>                                   |
| 17 (0x11)    | Auxiliary Access — Upload Request (Tool Requests Information) Message. Refer to <a href="#">Section 24.6.3, "Accessing READI Tool Mapped Registers Via the Auxiliary Port."</a>                     |
| 18 (0x12)    | Auxiliary Access — Download Request (Tool Provides Information) Message. Refer to <a href="#">Section 24.6.2, "Accessing Memory-Mapped Locations Via the Auxiliary Port."</a>                       |
| 19 (0x13)    | Auxiliary Access — Upload/Download Information (Device/Tool Provides Information) Message. Refer to <a href="#">Section 24.6.3, "Accessing READI Tool Mapped Registers Via the Auxiliary Port."</a> |
| 27 (0x1B)    | Program Trace <sup>1</sup> - Resource Full Message. Refer to <a href="#">Section 24.8.2.4.5, "Resource Full Message."</a> <sup>1</sup>                                                              |

<sup>1</sup> This message is not available on the MPC561 prior to revision D and is not available on the MPC563 revision B and earlier.

**Table 24-2. Vendor-Defined Messages**

| TCODE Number | Message Name                                                                                   |
|--------------|------------------------------------------------------------------------------------------------|
| 56 (0x38)    | RCPU Development Access — DSDI Data (Tool Provides Information) Message                        |
| 57 (0x39)    | RCPU Development Access — DSDO Data (Device Provides Information) Message                      |
| 58 (0x3A)    | RCPU Development Access — BDM Status (Device Provides Information) Message                     |
| 59 (0x3B)    | Program Trace — Indirect Branch Message With Compressed Code. Available in MPC562/MPC564 only. |

**Table 24-2. Vendor-Defined Messages (continued)**

| TCODE Number | Message Name                                                                                                   |
|--------------|----------------------------------------------------------------------------------------------------------------|
| 60 (0x3C)    | Program Trace — Direct Branch Synchronization Message With Compressed Code. Available in MPC562/MPC564 only.   |
| 61 (0x3D)    | Program Trace — Indirect Branch Synchronization Message With Compressed Code. Available in MPC562/MPC564 only. |

Vendor-defined messages outlined in [Table 24-2](#) are also supported by READI.

## 24.5 Terms and Definitions

**Table 24-3. Terms and Definitions**

| Term                         | Description                                                                                                                                                                                                                |
|------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Auxiliary Port               | Refers to IEEE-ISTO 5001 auxiliary port.                                                                                                                                                                                   |
| Branch Trace Messaging (BTM) | External visibility of addresses for taken branches and exceptions, and the number of sequential instructions executed between each taken branch.                                                                          |
| BDM                          | Background Debug Mode.                                                                                                                                                                                                     |
| Compressed Code Mode         | Current instruction stream is fetching compressed code. Available in MPC562/MPC564 only.                                                                                                                                   |
| Calibration Constants        | Performance related constants which must be tuned for automotive powertrain and disk drive applications.                                                                                                                   |
| Calibration Variables        | Intermediate calculations which must be visible during the calibration or tuning process to enable accurate tuning of calibration constants.                                                                               |
| Data Read Message (DRM)      | External visibility of data reads to internal memory-mapped resources.                                                                                                                                                     |
| Data Write Message (DWM)     | External visibility of data writes to internal memory-mapped resources.                                                                                                                                                    |
| Data Trace Messaging (DTM)   | External visibility of how data flows through the embedded system. May include DRM and/or DWM.                                                                                                                             |
| Download                     | Tool sends information to the device                                                                                                                                                                                       |
| Field                        | Number of bits representing single piece of information                                                                                                                                                                    |
| FPM                          | Full Port Mode. This is the default full port mode for READI.                                                                                                                                                              |
| IEEE-ISTO 5001               | IEEE-ISTO 5001, formerly known as Global Embedded Processor Debug Interface Standard. Worldwide web documentation at <a href="http://www.nexus5001.org/">http://www.nexus5001.org/</a> .                                   |
| Halt                         | RCPU is in freeze state (typically in debug mode)                                                                                                                                                                          |
| Instruction Fetch            | The process of reading the instruction data received from the instruction memory.                                                                                                                                          |
| Instruction Issue            | The process of driving valid instruction bits inside the processor. The instruction is decoded by each execution unit, and the appropriate execution unit prepares to execute the instruction during the next clock cycle. |

**Table 24-3. Terms and Definitions (continued)**

| Term                          | Description                                                                                                                                                                                                                                                                           |
|-------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Instruction Taken             | An instruction is taken after it has been issued and recognized by the appropriate execution unit. All resources to perform the instruction are ready, and the processor begins to execute it.                                                                                        |
| Instruction Retire            | Completion of the instruction issue, execution and writeback stages. An instruction is ready to be retired if it completes without generating an exception and all instructions ahead of it in history buffer have completed without generating an exception.                         |
| ICTRL                         | Instruction bus support control register (Refer to <a href="#">Table 23.6.11</a> )                                                                                                                                                                                                    |
| Ownership Trace Message (OTM) | Visibility of process/function that is currently executing.                                                                                                                                                                                                                           |
| Public Messages               | Messages on the auxiliary signals for accomplishing common visibility and controllability requirements e.g. DRM and DWM.                                                                                                                                                              |
| RCPU                          | Processor that implements the PowerPC-based architecture used in the Freescale MPC500 family of microcontrollers.                                                                                                                                                                     |
| READI                         | Real time Embedded Applications Development Interface.                                                                                                                                                                                                                                |
| READI signals                 | Refers to IEEE-ISTO 5001 auxiliary port.                                                                                                                                                                                                                                              |
| RPM                           | Reduced Port Mode. This is the reduced port mode for READI.                                                                                                                                                                                                                           |
| run-time                      | RCPU is executing program code in normal mode                                                                                                                                                                                                                                         |
| Sequential Instruction        | Any instruction other than a flow-control instruction or isync.                                                                                                                                                                                                                       |
| Snooping                      | Monitoring addresses driven by a bus master to detect the need for coherency actions.                                                                                                                                                                                                 |
| Standard                      | The phrase “according to the standard” implies according the IEEE-ISTO 5001 - 1999.                                                                                                                                                                                                   |
| Superfield                    | One or more message “fields” delimited by $\overline{\text{MSEO}}$ / $\overline{\text{MSEI}}$ assertion/negation. The information transmitted between “start-message” and “end-packet” states.                                                                                        |
| Show Cycle                    | An internal access (e.g., to an internal memory) reflected on the external bus using a special cycle (marked with a dedicated transfer code). For an internal memory “hit,” an address-only bus cycle is generated; for an internal memory “miss,” a complete bus cycle is generated. |
| Transfer Code (TCODE)         | Message header that identifies the number and/or size of packets to be transferred, and how to interpret each of the packets.                                                                                                                                                         |
| TCK / DSCK / MCKI             | Multiplexed signal: JTAG Clock or Development Port Clock. MCKI is a READI signal on the MPC561/MPC563                                                                                                                                                                                 |
| TDI / DSDI / MDI0             | Multiplexed signal: JTAG Data In or Development Port Serial Data In. MDI0 is a READI signal on the MPC561/MPC563.                                                                                                                                                                     |
| TDO / DSDO / MDO0             | Multiplexed signal: JTAG Data Out or Development Port Serial Data Out. MDO0 is a READI signal on the MPC561/MPC563                                                                                                                                                                    |
| Upload                        | Device sends information to the tool.                                                                                                                                                                                                                                                 |
| VSYNC                         | Internal RCPU signal                                                                                                                                                                                                                                                                  |
| VF                            | Internal RCPU signal which indicates instruction queue status.                                                                                                                                                                                                                        |
| VFLS                          | Internal RCPU signal which indicates history buffer flush status.                                                                                                                                                                                                                     |

## 24.6 Programming Model

The READI registers do not follow the recommendations of the IEEE-ISTO 5001 - 1999, but are loosely based on the 0.9 release of the standard. See <http://www.nexus5001.org/>.

READI registers are classified into two categories: user-mapped register and tool-mapped registers.

User-mapped register (a memory-mapped register):

- Ownership trace register

Tool-mapped registers (registers which can be accessed only through the development tool and are not memory mapped):

- Device ID register
- Development control register
- Mode control register 4-bit
- User base address register
- Read/write access register
- Upload/download information register
- Data trace attributes register 1
- Data trace attributes register 2

### 24.6.1 Register Map

READI registers are accessible via the auxiliary port. They can be classified into two categories: user-mapped registers and tool-mapped registers.

#### 24.6.1.1 User-Mapped Register (OTR)

The operating system writes the ID for the current task/process in the single user-mapped register, the READI ownership trace (OTR) register. [Table 24-4](#) shows the location of the register bits. Their functions are explained below.

The current task/process (CTP) field is updated by the operating system software to provide task/process ID information. The OTR register can only be accessed by supervisor data attributes. Only CPU writes to this register will be transmitted. This register is not accessible via the auxiliary port download request message.

#### NOTE

This is the only READI register that is reset by  $\overline{\text{HRESET}}$ .

**Figure 24-2. READI Ownership Trace Register (OTR)**

**Table 24-4. OTR Bit Descriptions**

| Bits | Name | Description                                 |
|------|------|---------------------------------------------|
| 0:31 | CTP  | READI ownership trace register, write only. |

### 24.6.1.2 Tool-Mapped Registers

Table 24-5 defines READI registers that are not memory mapped and can only be accessed through the development tool. Their corresponding access opcodes are also defined.

**Table 24-5. Tool-Mapped Register Space**

| Access Opcode | Register                                   | Access Type             |
|---------------|--------------------------------------------|-------------------------|
| 8 (0x08)      | Device ID Register (DID)                   | Read Only               |
| 10 (0x0A)     | Development Control Register (DC)          | Read Only               |
| 11(0x0B)      | Mode Control Register (MC) <sup>1</sup>    | Read/Write <sup>1</sup> |
| 13 (0x0D)     | User Base Address Register (UBA)           | Read Only               |
| 15 (0x0F)     | Read/Write Access Register (RWA)           | Read/Write              |
| 16 (0x10)     | Upload/Download Information Register (UDI) | Read/Write              |
| 20 (0x14)     | Data Trace Attributes Register 1 (DTA1)    | Read/Write              |
| 21 (0x15)     | Data Trace Attributes Register 2 (DTA2)    | Read/Write              |

<sup>1</sup> Not available on all revisions. Refer to the device errata for the version of silicon in use.

### 24.6.1.3 Device ID Register (DID)

Accessing the DID register provides key attributes to the development tool concerning the MCU. This information is also transmitted via the auxiliary output port upon exit of READI reset ( $\overline{\text{RSTI}}$ ), if  $\overline{\text{EVTI}}$  is asserted at  $\overline{\text{RSTI}}$  negation. Table 24-6 gives the bit descriptions.

<sup>1</sup> The default value depends on the revision of the device.  
<sup>2</sup> XXX = 0b101 for MPC561/MPC562 and XXX = 0b110 for MPC563/MPC564.

**Figure 24-3. READI Device ID Register**

**Table 24-6. DID Bit Descriptions**

| RCPU Bits | Nexus Bits | Name             | Description                                                                                                                                                                                                                                                          |
|-----------|------------|------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:3       | 31:28      | REV              | READI version number. This field contains the revision level of the device.                                                                                                                                                                                          |
| 4:9       | 27:22      | MDC <sup>1</sup> | READI Manufacturer Design Center. This field identifies the manufacturer's design center. The MPC561/MPC563 has a value of 0x02.                                                                                                                                     |
| 10:19     | 21:12      | PN <sup>1</sup>  | READI Part Number. This part number identification field. The MPC561/MPC562 field value is 0x35, and MPC563/MPC564 value is 0x36.                                                                                                                                    |
| 20:30     | 11:1       | MID              | READI Manufacturer ID. This field identifies the manufacturer of the device, Freescale's ID is 0x0E.<br>The value of this register for the MPC561 prior to Revision D silicon is 0x1C, and the value for the MPC563 prior to Revision B and earlier silicon is 0x1C. |
| 31        | 0          | —                | Reserved                                                                                                                                                                                                                                                             |

<sup>1</sup> The IEEE-ISTO 5001-1999 defines these two fields as a single combined field.

### 24.6.1.4 Development Control Register (DC)

The DC register is used for basic development control of the READI module. [Table 24-7](#) shows the location of register bits.

**Figure 24-4. READI Development Control (DC) Register**

**Table 24-7. DC Bit Descriptions**

| RCPU Bits | Nexus Bits | Name             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

| 6:7       | 1:0        | EC               | READI $\overline{\text{EVTI}}$ Control Field can be configured for synchronization and breakpoint generation. If the EC is equal to 0b00, asserting $\overline{\text{EVTI}}$ will cause the next program and data trace message to be a synchronization message (providing program and data trace are enabled). If the EC field is equal to 0b01, a breakpoint will be generated. If the field is configured to one of the reserved states, its action reverts to that of the default state.<br>NOTE: The $\overline{\text{EVTI}}$ signal is level sensitive when EC is configured for breakpoint generation. This implies that as long as $\overline{\text{EVTI}}$ assertion is continued (with EC set to 0b01), the READI module will continue requesting a breakpoint. The user must detect breakpoint generation and negate the $\overline{\text{EVTI}}$ signal appropriately.<br>00 $\overline{\text{EVTI}}$ for program and data trace synchronization<br>01 $\overline{\text{EVTI}}$ for breakpoint generation<br>1x No Action |

<sup>1</sup> The DOR and DME fields in the DC register can only be modified when system reset is asserted, or reset (to default state) when the READI module is reset by the assertion of  $\overline{\text{RSTI}}$ .

Table 24-8 describes the DC register fields with the mode configurations for RCPU development access.

**Table 24-8. RCPU Development Access Modes**

| DOR | DME | RCPU Development Access through READI                                                               |
|-----|-----|-----------------------------------------------------------------------------------------------------|
| x   | 0   | Non-debug mode access of RCPU development through READI.                                            |
| 0   | 1   | Debug mode is enabled through READI (RCPU is still in normal mode, out of reset)                    |
| 1   | 1   | Debug mode is enabled through READI and entered out-of-reset. Debug mode entry causes RCPU to halt. |

### 24.6.1.5 Mode Control Register (MC)

The MC register is used to select different modes of the READI module. Table 24-7 shows the location of register bits.

### NOTE

The MC register is not available prior to Revision D of the MPC561 and is not available in Revision B and earlier versions of the MPC563. Prior revisions have only the default features.

Figure 24-5. READI Mode Control (MC) Register

Table 24-9. MC Bit Descriptions

| RCPU Bits | Nexus Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|-----------|------------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0         | 7          | QTST | Enables a factory test mode for structural testing of the queue. This bit can only be written in factory test mode. When set, no trace messages are queued. Users should always write this bit as a 0.                                                                                                                                                                                                                                                               |
| 5         | 2          | PTM  | The Program Trace Mode (PTM) bit enables an enhanced method of program trace. This mode allows program trace to work with the ISCTL bits of the ICTRL register set to any value except 3. The value of 2 is recommended for optimal processor performance. The drawback of this mode is direct branch messages are never synchronizing so sync requests must be held until the next indirect branch.<br>0 Legacy Program Trace Mode<br>1 Enhanced Program Trace Mode |
| 6         | 1          | QFM  | The Queue Flush Mode (QFM) bit selects if information in the queue is discarded or transmitted at the time of an overrun. Discarding information allows trace to resume quicker after an overrun, but makes it difficult to find the cause of the overrun.<br>0 Information in the queue is removed<br>1 Trace is stopped until the queue empties.                                                                                                                   |
| 7         | 0          | PTSM | The Program Trace Sync Mode (PTSM) indicates if the program trace messages contain the I-CNT packet.<br>0 Program trace message do not contain the I-CNT packet.<br>1 Program trace message contain the I-CNT packet.                                                                                                                                                                                                                                                |

#### 24.6.1.6 User Base Address Register (UBA)

The UBA register defines the memory map address for the OT register. [Table 24-10](#) gives a description of the register bits.

Figure 24-6. READI User Base Address Register

Table 24-10. UBA Bit Descriptions

| RCPU Bits | Nexus Bits | Name | Description                                                                                                                                                                                   |
|-----------|------------|------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:31      | 31:0       | UBA  | The user base address (UBA) field defines the memory map address for the OT register. The MPC561/MPC563 user base address is 0x38002C. The UBA register is read-only by the development tool. |

24.6.1.7 Read/Write Access Register (RWA)

The RWA register provides DMA-like access to memory-mapped locations, MPC500 special purpose registers, and READI tool mapped registers. [Table 24-11](#) shows the location of register bits.

Figure 24-7. READI Read/Write Access Register

Table 24-11. RWA Read/Write Access Bit Descriptions

| RCPU Bits | Nexus Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                    |
|-----------|------------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0         | 79         | SC   | The start complete (SC) field is set when a read or write access is initiated. The device will clear the SC bit once the read or write access completes. During a block access, if the SC bit is reset, the access will terminate.<br>0 Access complete<br>1 Start access                                                                                      |
| 1:25      | 78:54      | RWAD | Read/write address (RWAD) bits are used to identify the address of internal memory-mapped resources to be accessed, or the lowest address (i.e., lowest unsigned value) for a block move (CNT > 0). The address range for a block move is from RWAD to RWAD + CNT.<br>NOTE: The RWD field of the UDI register is shared with the WD field of the RWA register. |
| 26        | 53         | RW   | The read/write (RW) field can be configured to allow selection of a read or a write access.<br>0 Read access<br>1 Write access                                                                                                                                                                                                                                 |

**Table 24-11. RWA Read/Write Access Bit Descriptions (continued)**

| RCPU Bits | Nexus Bits | Name | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|-----------|------------|------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 27:28     | 52:51      | SZ   | The word size (SZ) field can be configured to allow 32-bit, 16-bit, or 8-bit read/write accesses. If the field is configured to one of the reserved states, its action reverts to that of the default state.<br>00 32-bit<br>01 16-bit<br>10 8-bit<br>11 Reserved                                                                                                                                                                                                                                              |
| 29:60     | 50:19      | WD   | Write data (WD) bits contain the data to be written. For a read access, the data stored is a don't care.                                                                                                                                                                                                                                                                                                                                                                                                       |
| 61:62     | 18:17      | PRV  | The Privilege Attribute Field can be configured to select different read/write access attributes.<br>00 User Data<br>01 User Instruction<br>10 Supervisor Data<br>11 Supervisor Instruction                                                                                                                                                                                                                                                                                                                    |
| 63        | 16         | MAP  | The Map Select Field can be configured to allow access to multiple memory maps. The primary processor memory map (MAP equal to 0b0) is designated as the default. The secondary memory map (MAP equal to 0b1) can be set to select the MPC500 special purpose registers.<br>0 Primary memory map<br>1 Secondary memory map (PPC Special Purpose Registers)                                                                                                                                                     |
| 64:79     | 15:0       | CNT  | The Access Count Field can be configured to indicate the number of accesses of word size (defined in SZ field). The CNT value is used to increment the specified address in the RWAD field for block read/write accesses.<br>For a single read/write access, the CNT value should equal to 0x0000. A 64-Kbyte block read/write access can be performed by configuring the CNT bits as 0xFFFF. If a user wants to terminate a block read or write access which has not completed, the CNT bits should be reset. |

### 24.6.1.8 Upload/Download Information Register (UDI)

The UDI register, a 34-bit register, is used to store the data to be written for block write access, and the data read for read (single and block) accesses. [Table 24-12](#) gives a description of the register bits.

**Figure 24-8. READI Upload/Download Information Register**

**Table 24-12. UDI Bit Descriptions**

| RCPU Bits | Nexus Bits | Name | Description                                                                                                                                                                                                                                                                                    |
|-----------|------------|------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0:31      | 33:2       | RWD  | The Read/Write Data Field is used to store data for read accesses and block write accesses. It can contain three sizes of data. Refer to <a href="#">Table 24-13</a> , <a href="#">Table 24-14</a> and <a href="#">Table 24-9</a> for details.                                                 |
| 32        | 1          | ERR  | The Error Field is used to determine the status of the read or write access. Refer to <a href="#">Table 24-13</a> and <a href="#">Table 24-14</a> for details.<br>0 Read or write access has not been completed.<br>1 Read or write access has completed.<br>NOTE: The ERR field is read-only. |
| 33        | 0          | DV   | The Data Valid Field is used to determine the status of the read or write access. Refer to <a href="#">Table 24-13</a> and <a href="#">Table 24-14</a> for details.<br>0 No error has occurred.<br>1 Access error occurred.<br>NOTE: The DV field is read-only.                                |

**Table 24-13. Read Access Status**

| ERR | DV | Status                                                 |
|-----|----|--------------------------------------------------------|
| 0   | 0  | Read access has not yet completed                      |
| 0   | 1  | Read access has completed and no access error occurred |
| 1   | 0  | Access error occurred                                  |
| 1   | 1  | Not allowed                                            |

**Table 24-14. Write Access Status**

| ERR | DV | Status                                                  |
|-----|----|---------------------------------------------------------|
| 0   | 0  | Write access has completed and no access error occurred |
| 1   | 0  | Write access error occurred (Error Message sent out)    |
| 0   | 1  | Write access has not yet completed                      |
| 1   | 1  | Not allowed                                             |

Figure 24-9. RWD Field Configuration

### NOTE

The RWD field of the UDI register is shared with the WD field of the RWA register.

## 24.6.1.9 Data Trace Attributes 1 and 2 Registers (DTA1 and DTA2)

The DTA1 and DTA2 registers allow data trace messaging (DTM) to be restricted to reads, writes or both for a user programmable address range. Two DTA registers allow two address ranges to be selected for DTM. Refer to [Table 24-15](#) for register bit descriptions.

|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |

|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |
|       |                          |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |

| DTSA = DTEA       | Word at DTSA   |

### NOTE

There is no way to distinguish between off-core MPC500 special purpose register (SPR) map and normal memory map accesses via the defined address range control. If data trace ranges are set up such that the off-core MPC500 SPR map falls within active ranges, then accesses to these off-core MPC500 SPRs will be traced, and the messages will not be distinguishable from accesses to normal memory map space. Off-core MPC500 SPRs typically exist in the 8- to 16-Kbyte lowest memory block (0x2000 – 0x3FF0). If data or peripherals are mapped to this space, load/stores to MPC500 SPRs will be indistinguishable from data or peripheral accesses.

## 24.6.2 Accessing Memory-Mapped Locations Via the Auxiliary Port

The control and status information is accessed via the four auxiliary access public messages: device ready for upload/download, upload request (tool requests information), download request (tool provides information), and upload/download information (device/tool provides information).

To write control or status to memory-mapped locations the following sequence would be required.

1. The tool confirms that the device is ready (so as to not cancel an ongoing read write access). The tool transmits the download request public message (TCODE 18) which contains write attributes, write data, and target address.
2. The tool waits for device ready for upload/download (TCODE 16) message before initiating next access.

To read control or status from memory-mapped locations the following sequence would be required.

1. The tool confirms that the device is ready. The tool transmits the download request public message (TCODE 18) which contains read attributes and target address.
2. When device reads data it transmits upload/download information message (TCODE 19) containing read data. Device is now ready for next access.

For a block write to memory-mapped locations the following sequence would be required.

1. The tool confirms that the device is ready. The tool transmits the download request public message (TCODE 18) which contains block write attributes, first write data, and target address.
2. The tool waits for device ready for upload/download message (TCODE 16). When it is transmitted by device, tool transmits upload/download information message (TCODE 19) containing next write data. This step is repeated until all data is written

For a block read from memory-mapped locations the following sequence would be required.

1. The tool confirms that the device is ready. The tool transmits the download request public message (TCODE 18) which contains block read attributes and target address.
2. The tool waits for upload/download information message (TCODE 19) from device, which contains read data. This step is repeated until all data is read.

Refer to [Section 24.10, “Read/Write Access,”](#) for more details on read/write access protocol.

### 24.6.3 Accessing READI Tool Mapped Registers Via the Auxiliary Port

To write control or status data to READI tool mapped registers the following sequence would be required.

1. The tool confirms that the device is ready. The tool transmits the download request message (TCODE 18) which contains write data, and register opcode.
2. The tool waits for device ready for upload/download message (TCODE 16) before initiating next access.

To read control or status from READI tool mapped registers the following sequence would be required

1. The tool confirms that the device is ready. The tool transmits the upload request message (TCODE 17) which contains the target opcode.
2. When device reads data it transmits upload/download information message (TCODE 19) containing read data. Device is now ready for next access.

Refer to [Section 24.10, “Read/Write Access,”](#) for more details on read/write access protocol.

### 24.6.4 Partial Register Updates

Registers may be updated via the auxiliary port using the download request message with the message containing only N (where N is less than register width) most-significant bits of the register. In such cases the bits not transmitted will be reset to 0b0. The bits transmitted will be aligned such that the last bit transmitted will be the most significant bit of the register. Therefore a message size that is divisible by the input port size should be transmitted.

## 24.6.5 Programming Considerations

The following programming guidelines are recommended for users of the READI features.

### 24.6.5.1 Program Trace Guidelines

Program trace via BTM is not supported during BDM.

For program trace synchronization to work, the ICTRL register (Refer to [Table 23.6.11](#)) must be programmed such that show cycles will be performed for all changes in the program flow (ISCTL field = 0b01) or the PTM bit in the READI MC register must be set and the ISCTL field in the ICTRL register must not equal 0b11.

#### NOTE

The user must program the ICTRL for change of flow show cycles or the PTM bit in the READI MC register early in the reset vector, before any branches, otherwise trace is not guaranteed.

If BDM is enabled, the ICTRL register cannot be modified through the program and can only be modified through RCPU development access.

To get the best performance from the system, PTM should be set to 1 and ISCTL should be set to 0b10. It is also recommended that the USIU be programmed to ignore instruction show cycles (so as to not impact U-bus performance). See [Section 6.2.2.1.1, “SIU Module Configuration Register \(SIUMCR\).”](#)

To correctly trace program execution using BTM, the READI module must be enabled prior to release of system reset. If the READI module is enabled ( $\overline{\text{EVTI}}$  asserted,  $\overline{\text{RSTI}}$  negated) after the RCPU has started execution of the program, the trace cannot be guaranteed. Refer to [Figure 24-16](#) for further details.

### 24.6.5.2 Compressed Code Mode Guidelines

To display data on instruction show cycles, the BBC must be enabled. BBCMCR[DECOMP\_SC\_EN] (refer to [Section 4.6.2.1, “BBC Module Configuration Register \(BBCMCR\)”](#)) must be set when decompression is enabled. This will allow READI to track the compressed code.

BBCMCR[DECOMP\_SC\_EN] should not be set if there is no intention to use compressed code, as it will degrade U-bus performance.

Refer to [Appendix A, “MPC562/MPC564 Compression Features”](#) for MPC562/MPC564 compression information.

The ICTRL register must be programmed such that a show cycle will be performed for all changes in the program flow (ISCTL field = 0b01), or the PTM bit must be set and ISCTL must be set to a value other than 0b11. (See [Table 23-26](#).)

## 24.7 Signal Interface

This section details information regarding the READI signals and signal protocol.

## 24.7.1 Functional Description

The READI signal interface provides the function of transmitting messages from the message queues to the external tools. The signal interface also provides the control for timing and logic for formatting the messages.

### 24.7.1.1 Signals Implemented

The READI module implements one MCKO, MCKI,  $\overline{\text{EVTI}}$ ,  $\overline{\text{RSTI}}$ ,  $\overline{\text{MSEO}}$ , and  $\overline{\text{MSEI}}$  signal. It also implements one or two MDI and two or eight MDO signals. The input signals are synchronized to the MCKI input clock and the output signals are synchronized to the free running MCKO output clock. The MCKI input clock should be synchronised to the MCKO output clock to ensure correct message reception. The READI signal definition is outlined in [Table 24-17](#).

#### NOTE

MCKI clock frequency has to be less than or equal to one half of MCKO clock frequency.

**Table 24-17. Description of READI Signals**

| IEEE-ISTO 5001 Signal Name | Input/Output | Description of Signal                                                                                                                                                                                                                                                                                                                             |
|----------------------------|--------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| MCKO                       | Output       | Message Clock-Out (MCKO) is a free-running output clock to development tools for timing of MDO and $\overline{\text{MSEO}}$ signal functions. MCKO is the same as the MCU system clock.                                                                                                                                                           |
| MDO[7:0] or MDO[1:0]       | Output       | Message Data Out (MDO[7:0] or MDO[1:0]) are output signals used for uploading OTM, BTM, DTM, and Read/Write Accesses. External latching of MDO will occur on rising edge of MCKO. Eight signals are implemented. MDO[7:0] are used in full port mode, MDO[1:0] are used in reduced port mode.                                                     |
| $\overline{\text{MSEO}}$   | Output       | Message Start/End Out ( $\overline{\text{MSEO}}$ ) is an output signal which indicates when a message on the MDO signals has started, when a variable length packet has ended, and when the message has ended. 1 $\overline{\text{MSEO}}$ signal is implemented. External latching of $\overline{\text{MSEO}}$ will occur on rising edge of MCKO. |
| MCKI                       | Input        | Message Clock-In (MCKI) is a input clock from development tools for timing of MDI and $\overline{\text{MSEI}}$ signal functions. MCKI frequency has to be less than or equal to one half of MCKO frequency.                                                                                                                                       |
| MDI[1:0] or MDIO           | Input        | Message Data In (MDI[1:0] or MDI[0]) are input signals used for downloading configuration information, writes to user resources, etc. Internal latching of MDI will occur on rising edge of MCKI. Two signals are implemented on the MPC561/MPC563. MDI[1:0] are used in full port mode, MDI[0] only is used in reduced port mode.                |
| $\overline{\text{MSEI}}$   | Input        | Message Start/End In ( $\overline{\text{MSEI}}$ ) is an input signal which indicates when a message on the MDI signals has started, when a variable length packet has ended, and when the message has ended. 1 $\overline{\text{MSEI}}$ signal is implemented. Internal latching of $\overline{\text{MSEI}}$ will occur on rising edge of MCKI.   |
| $\overline{\text{EVTI}}$   | Input        | Event In ( $\overline{\text{EVTI}}$ ) — The $\overline{\text{EVTI}}$ signal is level sensitive when configured for breakpoint generation, otherwise it is edge sensitive.                                                                                                                                                                         |
| $\overline{\text{RSTI}}$   | Input        | Reset In ( $\overline{\text{RSTI}}$ ).                                                                                                                                                                                                                                                                                                            |

## 24.7.2 Functional Block Diagram

Figure 24-11 depicts the functional block diagram of the signal interface.

**Figure 24-11. Functional Diagram of Signal Interface**

The signal interface is responsible for handshaking with the message queue and registers. It is also responsible for requesting new messages from the message queue. A message is always requested from the message queue if the message queue is not empty, the message buffer is available and a higher priority message is not requesting to be transmitted. The rate at which data is removed from the queue depends on the average message length, the number of MDO signals, and the MCKO clocking rate.

## 24.7.3 Message Priority

Message formatting is performed in the signal interface block. The following priority scheme is implemented for messages sent to the signal output formatter block, with 1 being the highest priority and 5 being the lowest priority:

1. Invalid message
2. READI register access handshakes (device ready/download information)
3. Watchpoint messages
4. Read/write access message
5. RCPU development access message

## 6. Queued messages (program trace, data trace, and ownership trace)

### 24.7.4 Signal Protocol

The protocol for the MCU receiving and transmitting messages via the auxiliary signals will be accomplished with the  $\overline{\text{MSEI}}$  and  $\overline{\text{MSEO}}$  signal functions respectively. The  $\overline{\text{MSEI}}$  signal will provide the protocol for the MCU receiving messages, and the  $\overline{\text{MSEO}}$  signal will provide the protocol for the MCU transmitting messages.

The  $\overline{\text{MSEI}}/\overline{\text{MSEO}}$  protocol is illustrated in Table 24-18.

**Table 24-18.  $\overline{\text{MSEI}}/\overline{\text{MSEO}}$  Protocol**

| Operation                     | $\overline{\text{MSEO}}/\overline{\text{MSEI}}$ State |
|-------------------------------|-------------------------------------------------------|
| Idle                          | "1"s at all clocks                                    |
| Start                         | Two "1"s followed by one "0"                          |
| Active                        | "0"s at all clocks during transmission of a message   |
| End of variable length packet | "0" followed by "1"                                   |
| End of packet and message     | "0" followed by two or more "1"s                      |

$\overline{\text{MSEI}}/\overline{\text{MSEO}}$  are used to signal the end of variable-length packets and messages. They are not required to indicate end of fixed length packets.  $\overline{\text{MSEI}}/\overline{\text{MSEO}}$  are sampled on the rising edge of MCKI and MCKO respectively.

Fixed width fields can be concatenated before variable length fields without regard to the individual fields starting or ending at message  $N$  bit boundaries. Variable width fields must end at message  $N$  bit boundaries (where  $N$  is MDI/MDO signals).

Figure 24-12 shows the basic relation between the MDO and  $\overline{\text{MSEO}}$  signals, and packet structure. MDO and  $\overline{\text{MSEO}}$  are sampled on the rising edge of MCKO.

**Figure 24-12. Auxiliary Signal Packet Structure for Program Trace Indirect Branch Message**

Figure 24-13 illustrates the state diagram for  $\overline{\text{MSEI}}/\overline{\text{MSEO}}$  transfers. In the End Message state, data on MDI/O is ignored.

|                                                                                 | 8                          | 80                         | Variable    | 1). For an access, depending on word size selected (SZ field in RWA register), variable-length packets of information (10, 18, or 34 bits) will be uploaded/downloaded from/to device.<br>2). Depending upon opcode selected for upload from internal READI registers, information to be uploaded to the device will vary. |                    |

<sup>1</sup> This message is provided only for the MPC562/MPC564.

### 24.7.5.1 Message Formats

Message formatting is performed in the signal interface block. Raw messages read from the message queue are independent of the number of MDO signals implemented.

Table 24-22 shows the various message formats that the signal interface formatter has to encounter.

## NOTE

For variable length fields, the transmitted size of the field is determined as the bits from the least significant bit to the most significant non-zero valued bit, (i.e., most significant 0 value bits are not transmitted).

**Table 24-22. Message Field Sizes<sup>1,2</sup>**

| Message                                                            | TCODE       | Field # 1                       | Field # 2                       | Field # 3 | Max Size <sup>3</sup> | Min. Size <sup>4</sup> |

| Program Trace—<br>Indirect Branch<br>Synchronization<br>Message With<br>Compressed Code (PTSM = 0) <sup>5</sup> | 61<br>(0x3D) | Fixed = 6                      | Variable<br>Max = 23<br>Min = 1 | NA                              | 35 bits               | 13 bits                |
| Program Trace—<br>Indirect Branch<br>Synchronization<br>Message With<br>Compressed Code (PTSM = 1) <sup>5</sup> | 61<br>(0x3D) | Variable<br>Max = 8<br>Min = 1 | Fixed = 6                       | Variable<br>Min = 1<br>Max = 23 | 43 bits               | 14 bits                |

<sup>1</sup> The double edges indicate that  $\overline{\text{MSEO/MSEI}}$  is asserted to indicate the start of a message or negated to indicate the end of a message. Refer to [Figure 24-14](#).

<sup>2</sup> The shaded edges indicate super fields that can hold information delimited via  $\overline{\text{MSEO/MSEI}}$  assertion followed by  $\overline{\text{MSEO/MSEI}}$  negation.

<sup>3</sup> Maximum information size. The actual number of bits transmitted is dependant on the number of MDO signals.

<sup>4</sup> Minimum information size. The actual number of bits transmitted is dependent on the number of MDO signals.

<sup>5</sup> Refer to [Table 24-20](#).

<sup>6</sup> Not available prior to Rev. D of the MPC561 and is not available in Rev. B and earlier versions of the MPC563

<sup>7</sup> Only available on MPC562/MPC564

The maximum message length is 94 bits. The maximum number of fields is three, excluding the TCODE itself.

### 24.7.5.2 Rules of Messages

- A variable sized field within a message must end on a port boundary.
- A variable sized field may start within a port boundary only when following a fixed length packet.
- Super fields must end on a port boundary (2-, 4-, or 8-bit boundaries depending on whether the device receives or sends messages, and the port size configured).
- When a variable length field is sized such that it does not end on a port boundary, it is necessary to extend and zero fill the remaining bits after the highest-order bit so that it can end on a port boundary.
- A data field within a data trace message must be 8, 16, 24, or 32 bits in length.

The field containing the TCODE number is always transferred out first, followed by subsequent fields of information. Within a field, the lowest significant bits are shifted out first. [Figure 24-14](#) shows the transmission sequence of a message which is made up of a TCODE (a fixed-length field) and a variable length field (FIELD 1), together making a super field. Every instance of a fixed length field followed by a variable field is a super field. [Figure 24-14](#), for example, shows two super fields. The only exception to

this rule are the development port access messages. See [Section 24.14.1, “RCPU Development Access Messaging,”](#) for further details.

Figure 24-14. Transmission Sequence of Messages

### 24.7.5.3 Branch Trace Message Examples

The following are examples of branch trace messages.

#### 24.7.5.3.1 Example of Indirect Branch Message

[Table 24-23](#) illustrates an example of how the indirect branch public message is transmitted. The example uses a 4-bit output port.

Note that T0, I0, and A0 are the least significant bits where:

- Tx = TCODE number (fixed)
- Ix = Number of sequential instructions (variable)
- Ax = Unique portion of the address (variable)

#### NOTE

During clock 7, the tool should ignore data on MDO signals.

**Table 24-23. Indirect Branch Message**

| Clock | MDO[3:0] |    |    |    | MSE0 |                               |
|-------|----------|----|----|----|------|-------------------------------|
|       | 3        | 2  | 1  | 0  | 1    | Idle                          |
| 0     | X        | X  | X  | X  | 1    | Idle (or end of last message) |
| 1     | T3       | T2 | T1 | T0 | 0    | Start Message                 |
| 2     | I1       | I0 | T5 | T4 | 0    | Normal Transfer               |
| 3     | I5       | I4 | I3 | I2 | 0    | Normal Transfer               |
| 4     | 0        | 0  | I7 | I6 | 1    | End Packet                    |
| 5     | A3       | A2 | A1 | A0 | 0    | Normal Transfer               |
| 6     | A7       | A6 | A5 | A4 | 1    | End Packet                    |
| 7     | 0        | 0  | 0  | 0  | 1    | End Message                   |
| 8     | T3       | T2 | T1 | T0 | 0    | Start Message                 |

### 24.7.5.3.2 Example of Direct Branch Message

Table 24-24 is an example of the minimum transmission of any message containing a variable length field (three clocks). The example uses a 4-bit output port.

Note that T0, and I0 are the least significant bits where:

Tx = TCODE number (fixed)

Ix = Number of sequential instructions (variable)

#### NOTE

During clock 3, the tool should ignore data on MDO signals.

**Table 24-24. Direct Branch Message**

| Clock | MDO[3:0] |    |    |    | MSE0 |               |
|-------|----------|----|----|----|------|---------------|
|       | 3        | 2  | 1  | 0  | 1    | Idle          |
| 1     | T3       | T2 | T1 | T0 | 0    | Start Message |
| 2     | I1       | I0 | T5 | T4 | 1    | End Packet    |
| 3     | 0        | 0  | 0  | 0  | 1    | End Message   |

### 24.7.5.4 Non-Temporal Ordering of Transmitted Messages

Trace messages sent out may not be in the sequence they actually occurred. The traces are monitored on the internal buses and these traces are captured as they occur and are sent out in the order they were captured and processed.

BTMs are in sequence and DTMs are in sequence, however, temporal order of DTMs interleaved with BTMs may not be accurate with regard to logical flow of code.

## 24.7.6 READI Reset Configuration

The READI reset configuration information is received via  $\overline{\text{EVTI}}$  and MDI0 to enable or disable the READI module and select the port size.  $\overline{\text{EVTI}}$  and MDI0 are sampled synchronously at the negation of  $\overline{\text{RSTI}}$ . Reset configuration information must be valid on  $\overline{\text{EVTI}}$  and MDI0 at least four clocks prior to the negation of  $\overline{\text{RSTI}}$ .

If  $\overline{\text{EVTI}}$  is sampled asserted at negation of  $\overline{\text{RSTI}}$ , the READI module will be enabled. This is illustrated in Figure 24-15.

READI control and status information will be reset and the auxiliary output port will be three-stated, when  $\overline{\text{RSTI}}$  is asserted. System reset will not reset the READI control and status information and not three-state the auxiliary output port.

Port size configuration is selected via the value of MDI0 at the negation of  $\overline{\text{RSTI}}$ . Table 24-25 describes the READI reset configuration options.

**Table 24-25. READI Reset Configuration Options**

| $\overline{\text{EVTI}}$ | MDI [0] | Configuration                                                   |
|--------------------------|---------|-----------------------------------------------------------------|
| 1                        | X       | Module Disabled. All outputs three-stated.                      |
| 0                        | 1       | Module Enabled, Default Full Port Configuration<br>2 MDI, 8 MDO |
| 0                        | 0       | Module Enabled, Reduced Port Configuration<br>1 MDI, 2 MDO      |

$\overline{\text{RSTI}}$  has a pull-down resistor in the pads. If the auxiliary port is not connected to a tool, READI module will be in reset state and not drive the auxiliary output port.

**Figure 24-15. READI Module Enabled**

**NOTE:**  
If background debug mode (BDM) is enabled, the ICTRL register cannot be modified through user program. This register can only be accessed through the development port.

Figure 24-16. Enabling Program Trace Out of System Reset

## 24.7.7 READI Signals

The READI signals support Nexus (IEEE-ISTO 5001-1999) auxiliary port interface for debug. There are two modes available, full port mode and reduced port mode. Reduced port mode allows for a 1 bit input stream and a 2 bit output stream. Full port mode allows for a 2 bit input stream and an 8 bit output stream. See Figure 24-11 for READI mode selection.

Steps to Enter READI (Nexus) mode:

1. Negate PORESET while holding JCOMP/ $\overline{\text{RSTI}}$  low.
2. Configure TMS/ $\overline{\text{EVTI}}$  and TDI/DSDI/MDI[0] while JCOMP/ $\overline{\text{RSTI}}$  is low. ( $\overline{\text{EVTI}}$  = low to enable Nexus)
3. Negate JCOMP/ $\overline{\text{RSTI}}$ .
4. If MDI[0] is high at JCOMP/ $\overline{\text{RSTI}}$  negation, then full port mode is enabled otherwise Reduced mode is selected.

To exit READI mode:

1. Reassert JCOMP/ $\overline{\text{RSTI}}$  to disable READI.

Figure 24-17. READI Mode Selection

### 24.7.7.1 Reset Configuration for Debug Mode

To enable RCPU development access via the READI signals, the reset sequence outlined below should be used:

- Assert READI reset ( $\overline{\text{RSTI}}$ ), event-in ( $\overline{\text{EVTI}}$ ) and system reset ( $\overline{\text{HRESET}}$ )
- Negate  $\overline{\text{RSTI}}$
- Upon negation of  $\overline{\text{RSTI}}$ , tool should configure the DOR, DME, and DPA fields in the DC register to desired setting.
- Tool negates  $\overline{\text{HRESET}}$  at least 16 system clocks after receiving the device ready message

Refer to Figure 24-84 for further details.

### 24.7.7.2 Reset Configuration for Non-Debug Mode

Refer to [Section 24.7.7.1, “Reset Configuration for Debug Mode,”](#) for details on reset configuration for non-debug mode. The only difference between non-debug mode reset configuration and debug mode reset configuration are the values of the DOR and DME fields in the DC register.

### 24.7.7.3 Secure Mode

Refer to [Section 24.2.2, “Security,”](#) for further details.

### 24.7.7.4 Disabled Mode

If  $\overline{\text{EVTI}}$  is negated at negation of  $\overline{\text{RSTI}}$ , the READI module will be disabled. No trace output will be provided, and output auxiliary signals will be three-stated. This is illustrated in [Figure 24-18](#).

**Figure 24-18. READI Module Disabled**

### 24.7.7.5 Guidelines for Transmitting Input Messages

- An error message is sent out when an invalid TCODE is detected by the signal input formatter. Refer to [Section 24.10.8.2, “Invalid Message,”](#) for further details.
- An error message is sent out when an invalid access opcode is detected in auxiliary input messages by the signal input formatter. Refer to [Section 24.10.8.3, “Invalid Access Opcode,”](#) for further details.
- If the TCODE is valid, then READI will expect that the correct number of packets have been received and no further checking will be performed. If the number of packets received by READI is not correct, READI response is not defined, unless the message is a download request message (refer to [Section 24.6.4, “Partial Register Updates,”](#) for further details).

# 24.8 Program Trace

This section details the program trace mechanism supported by READI for the RCPU. Program trace is implemented via branch trace messaging (BTM) as per the IEEE-ISTO 5001-1999 definition.

## 24.8.1 Branch Trace Messaging

Branch trace messaging facilitates program trace by providing the following types of information:

- Messaging for taken direct branches includes how many sequential instructions were executed since the last taken branch or exception. Direct (or indirect) branches not taken are counted as sequential instructions.
- Messaging for taken indirect branches and exceptions includes how many sequential instructions were executed since the last taken branch or exception and the unique portion of the branch target address or exception vector address.
- For some mispredicted branches and exception occurrences, program trace correction messages correct the number of instructions since last taken branch as transmitted in prior BTM message.

### 24.8.1.1 RCPU Instructions that Cause BTM Messages

The following RCPU instructions, when executed, cause indirect branch messages to be encoded:

1. Taken branch relative to link or counter registers
2. Context switching sequential instructions
3. Exception taken (error/interrupts)

The following RCPU instruction, when executed, causes direct branch messages to be encoded:

1. Taken direct branch instructions

## 24.8.2 BTM Message Formats

BTM messages are of five types — direct, indirect, correction, synchronization, and error.

### 24.8.2.1 Direct Branch Messages

Direct branches (conditional or unconditional) are all taken branches whose destination is fixed in the instruction opcode.

The program trace direct branch message has the following format:

**Figure 24-19. Direct Branch Message Format**

## 24.8.2.2 Indirect Branch Messages

Indirect branches include interrupts, exceptions, and all taken branches whose destination is determined at run time. For the RCPU, certain sequential instructions are tagged with the indirect change-of-flow attribute because these instructions affect the machine in a similar manner to true indirect change-of-flow instructions. These instructions are the rfi, isync, mtmsr and certain mtspr (to CMPA – CMPF, ICTRL, ECR and DER)

The program trace indirect branch message has the following format:

**Figure 24-20. Indirect Branch Message Format**

For compressed code support, six additional bits indicate the starting bit address within the word of the compressed instruction.

The program trace indirect branch with compressed code message has the format shown in [Figure 24-21](#). The format of the bit address field is shown in [Figure 24-22](#). The bit definitions are shown in [Table 24-26](#).

### NOTE

On the MPC562/MPC564, the bit pointer should be multiplied by 2 (shift left on bit) for the actual starting bit position.

**Figure 24-21. Indirect Branch Message Format with Compressed Code**

**Figure 24-22. Bit Pointer Format with Compressed Code**

**Table 24-26. Bit Pointer Format**

| RCPU Bits | Nexus Bits | Name | Description                                                                                |
|-----------|------------|------|--------------------------------------------------------------------------------------------|
| 4:5       | 0:1        | —    | Reserved (Unused)                                                                          |
| 0:3       | 2:5        | BP   | Bit pointer. This value is 1/2 of the actual bit position on which the instruction starts. |

### 24.8.2.3 Correction Messages

In case of a mispredicted branch or an exception, a program trace correction message may also be sent indicating a number which corrects the number of instructions (not messages) in the trace.

In the case of a synchronizing branch trace message getting corrected due to a misprediction or an exception, the next branch trace message will be a synchronizing message.

Table 24-27 illustrates an example of a program trace correction message in case of a mispredicted branch.

#### NOTE

In case of a mispredicted branch, the correction count is always 1 and the sequential instruction count is reset to 1 (to denote the not-taken branch as a sequential instruction), after the program trace correction message is sent. This is because a mispredicted branch is considered to be a sequential instruction.

Table 24-28 illustrates an example of a program trace correction message in case of an exception.

#### NOTE

In case of an exception, the sequential instruction count is reset to 0, after the program trace correction message is sent.

**Table 24-27. Program Trace Correction Due to a Mispredicted Branch**

| Time | Processor State                                  | Message sent                                                                                                                                           |
|------|--------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------|

| 13                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | Sequential Instruction                 |                                                                                                                                                        |
| 14                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | Exception due to instruction at Time 8 | Program Trace Correction Message<br>TCODE = 10<br>Number of instructions to rewind from trace = 5                                                      |
| 16                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | Indirect Branch Instruction            | Indirect Branch Message<br>TCODE = 4<br>Number of sequential instructions executed since last taken branch = 0<br>Unique portion of the target address |
| <p>At Time 8, the Sequential instruction that causes an exception is issued.<br/>           At Time 14, the instruction issued at Time 8 causes an exception. A Program Trace Correction Message is sent out correcting the number of instructions in the trace (5). The sequential instruction that occurred at Time 13 is not included in the correction count because the tool is not aware that it occurred (it was not transmitted out).<br/>           Note: The sequential instruction at Time 8 did not retire and is included in the correction number.</p> |                                        |                                                                                                                                                        |

The program trace correction message has the following format:

**Figure 24-23. Program Trace Correction Message Format**

### 24.8.2.4 Synchronization Messages

A program trace synchronization message is transmitted via the auxiliary port (provided program trace is enabled) for the following conditions:

- Initial program trace message upon exit of any system reset will be a synchronization message.
- Upon exit of sleep, deep-sleep and low power down mode, the first BTM will be a synchronization message.
- Initial program trace message upon exit of background debug mode. Upon exiting BDM, the next BTM will be a synchronization message.
- When BTM is enabled, the first BTM will be a synchronization message.
- After 255 program trace messages have been queued without synchronization, the next BTM will be a synchronization message.

- Upon assertion of an event In ( $\overline{\text{EVTI}}$ ) signal. If the READI module is not disabled, an  $\overline{\text{EVTI}}$  assertion will cause the next BTM to be a synchronization message (provided the EC field is 0b00 in the DC register).
- Upon occurrence of a watchpoint, the next BTM will be a synchronization message (provided program trace is enabled).
- Occurrence of queue overrun. A program trace overrun error occurs when a trace message cannot be queued due to the queue being full. This causes the message queue to be flushed, and an error message is placed as the first message in the queue. The error code within the error message will indicate that program/data/ownership trace overrun has occurred. The next BTM will be a synchronization message.
- Sequential instruction count overflow. When the sequential instruction counter reaches its maximum count (up to 256 sequential instructions may be executed), the next BTM will be a program trace synchronization message. The sequential instruction counter is reset.
- Upon entering or exiting code compression mode, the next BTM will be a synchronization message.
- The next change-of-flow instruction fetch following VSYNC will be a synchronization message.

Program trace synchronization messages provide the full address (without leading zeros) and ensure that development tools fully synchronize with program trace regularly. Synchronization messages provide a reference address for subsequent BTMs, in which only the unique portion of the program trace address is transmitted.

### NOTE

For program trace synchronization to work, the ICTRL register (refer to [Table 23.6.11](#)) must be programmed such that show cycle will be performed for all changes in the program flow (ISCTL field = 01) if the PTM bit is set to 0. If the PTM bit is set to 1, ISCTL can be programmed to any value except no show cycles (ISCTL field = 11).

It is also recommended that the USIU be programmed to ignore instruction show cycles so as to not impact U-bus performance; set SIUMCR[NOSHOW]. Synchronization will only occur at changes in program flow boundaries, and cannot be forced by the READI module. Synchronizations on errors, overflows, as well as periodic synchronizations will not be deterministic to the nearest instruction, but to the next taken change in program flow. The start of program trace (enabled via any means) will be also deferred to the next change in program flow.

Program trace synchronization messages are of the following types:

- Direct branch
- Indirect branch
- Direct branch with compressed code
- Indirect branch with compressed code
- Resource full

### 24.8.2.4.1 Direct Branch Synchronization Message

The program trace direct branch synchronization message has the following formats depending on how the PTSM bit in the MC register is configured:

**Figure 24-24. Direct Branch Synchronization Message Format (PTSM = 0)**

**Figure 24-25. Direct Branch Synchronization Message Format (PTSM = 1)**

### 24.8.2.4.2 Indirect Branch Synchronization Message

The program trace indirect branch synchronization message has the following formats depending on the setting of MC[PTSM]:

**Figure 24-26. Indirect Branch Synchronization Message Format (PTSM = 0)**

**Figure 24-27. Indirect Branch Synchronization Message Format (PTSM = 1)**

### 24.8.2.4.3 Direct Branch Synchronization Message With Compressed Code

For compressed code support, six additional bits indicate the starting bit address within the word of the compressed instruction. The program trace direct branch synchronization with compressed code message has the following formats depending on the setting of MC[PTSM]:

Max Length = 35 bits

Min Length = 13 bits

**Figure 24-28. Direct Branch Synchronization Message Format with Compressed Code (PTSM = 0)**

Max Length = 43 bits

Min Length = 14 bits

**Figure 24-29. Direct Branch Synchronization Message Format with Compressed Code (PTSM = 1)**

#### 24.8.2.4.4 Indirect Branch Synchronization Message with Compressed Code

For compressed code support, six additional bits indicate the starting bit address within the word of the compressed instruction. The program trace indirect branch synchronization with compressed code message has the following formats depending on the setting of MC[PTSM]:

Max Length = 35 bits

Min Length = 13 bits

**Figure 24-30. Indirect Branch Synchronization Message Format with Compressed Code (PTSM = 0)**

Max Length = 43 bits

Min Length = 14 bits

**Figure 24-31. Indirect Branch Synchronization Message Format with Compressed Code (PTSM = 1)**

Bit pointer format is shown in [Figure 24-22](#) and bit address format is described in [Table 24-26](#).

#### 24.8.2.4.5 Resource Full Message

When more than 256 instructions have run without a branch being taken a program trace resource full message will be generated that indicates the maximum I-CNT value has been reached. The I-CNT field has a maximum width of 8 bits.

The total instruction count can be found by adding 256 for each program trace full message received to the sequence count of the direct or indirect branch trace message that follows the resource full message. The program trace full message has the following format:

**Figure 24-32. Program Trace Full Message Format**

At this time, the program trace sequential count full code is the only defined option for this message.

**Table 24-29. Resource Codes**

| Error Code | Description                         |
|------------|-------------------------------------|
| 0000       | Program Trace Sequential Count Full |
| 0001-1111  | Vendor Defined or Reserved          |

### 24.8.2.5 Error Messages

Branch trace error messages are explained within applicable functional areas, such as data trace, watchpoint, and program trace sections of this chapter.

### 24.8.2.6 Relative Addressing

The relative address feature is compliant with the IEEE-ISTO 5001 - 1999 recommendations, and is designed to reduce the number of bits transmitted for addresses of indirect branch messages.

The address transmitted is relative to the address of the previous branch trace message. It is generated by XORing the new address with the previous address, and then using only the results up to the most significant '1' in the result. To recreate this address, an XOR of the (most-significant 0-padded) message address with the previously decoded address gives the current address. [Figure 24-33](#) shows how a relative address is generated and how it can be used to recreate the original address.

Figure 24-33. Relative Address Generation and Re-Creation

### 24.8.3 Queue Overflow Program Trace Error Message

A trace overrun error occurs when a trace message cannot be queued due to the queue being full, provided program trace is enabled.

The overrun error causes the message queue to be flushed, and an error message to be queued. The error code within the error message indicates that either a program/data/ownership trace overrun error has occurred or that only a program trace overrun has occurred. The next BTM will be a synchronization message. Refer to [Table 24-20](#).

The error message has the following format:

Figure 24-34. Error Message (Queue Overflow) Format

### 24.8.4 Branch Trace Message Operation

#### 24.8.4.1 BTM Capture and Encoding Algorithm

BTM is accomplished by capturing instruction fetch information from the U-bus and instruction execution information from the RCP (VF and VFSL signals), and combining them to generate program trace messages.

### 24.8.4.2 Instruction Fetch Snooping

Instruction fetches are snooped on the U-bus. There is a one-to-one correspondence between instruction fetches marked with the U-bus program trace attribute and the indication of RCPU VF signal (only 3, 4, 5, and 6) between two synchronization events.

Since U-bus program trace attribute occurs after the indication of VF, it is latched and paired with the nearest (previous) unpaired VF (3, 4, 5, and 6) indication to determine the instruction address.

For all other VF indications, except 3, 4, 5, and 6, it is not possible to determine the instruction address.

### 24.8.4.3 Instruction Execution Tracking

Instruction execution tracking is performed by capturing the RCPU VF and VFLS signals, and decoding them to infer the state of the processor. The RCPU VF signals indicate two classifications of information:

- The current instruction type which is being loaded into the RCPU instruction queue. For further details refer to the *RCPU Reference Manual*.
- The number of instructions which are currently being flushed from the RCPU instruction queue. For further details refer to the *RCPU Reference Manual*.

### 24.8.4.4 Instruction Flush Cases

The various conditions under which the RCPU may signal instruction flushes of the RCPU prefetch queue or RCPU history buffer are:

1. A taken branch (direct, indirect, interrupt or exception) will cause the instruction prefetch queue (which contains instructions from the now old stream) to be flushed, and fetching will start from the branch target stream. The sequential instruction count will be updated to reflect this.
2. A mispredicted branch will cause instructions fetched from the new stream to be flushed, and fetching will resume from the old stream. It will also require a program trace message to be cancelled and the trace to be corrected.
3. An exception can cause cancellation of multiple taken branches which may require cancelling multiple program trace messages.

### 24.8.5 Branch Trace Message Queueing

READI implements a queue 16 or 32 messages deep (depending on the silicon version) for program trace, data trace, and ownership trace messages. Messages that enter the queue are transmitted via the output auxiliary port in the order in which they are queued.

#### NOTE

If multiple trace messages need to be queued at the same time, program trace messages will have the highest priority unless the data trace buffers are full, in which case the data trace messages are given temporary higher priority than the program trace messages.

## 24.8.7 Program Trace Guidelines

Refer to [Section 24.6.5.1, “Program Trace Guidelines,”](#) for further details.

# 24.9 Data Trace

This section details the data trace mechanism supported by READI. Data trace is implemented via data write messaging (DWM) and data read messaging (DRM), as per the IEEE-ISTO 5001 - 1999.

## 24.9.1 Data Trace for the Load/Store Bus (L-Bus)

The L-bus allows the RCPU to perform loads and stores, and the L2U to read and write the L-bus resources. Snooping for data trace on the L-bus requires the READI module to handle the full range of L-bus cycles. This includes various cases of pipelining and aborted cycles.

Data trace requires snooping the L-bus cycles, and storing the information for qualifying accesses (based on enabled features and matching target addresses). The READI module traces all data accesses that meet the selected range and attributes. This includes all RCPU initiated accesses and all L-bus accesses.

L-bus data cycles can have data sizes of 8, 16, or 32 bits. The READI module supports all three data sizes. In full port mode, 16-bit accesses shift out 24 bits of data so the tool can differentiate them from 8-bit accesses.

### NOTE

In early versions of the READI module, 8-bit data cannot be differentiated from 16-bit data when the 8 MSBs are set to zero. See the device mask set errata list for customer information.

## 24.9.2 Data Trace Message Formats

Data trace messages are of five types:

- Data write
- Data read
- Data write synchronization
- Data read synchronization
- Error message

### 24.9.2.1 Data Write Message

The data write message contains the data write value and the address of the target location, relative to the previous data trace message.

The data write message has the following format:

| [6 bits]  | [1 to 25 bits]   | [8, 16, or 32 bits] |
|-----------|------------------|---------------------|
| TCODE (5) | Relative Address | Data Value          |

Max Length = 63 bits  
Min Length = 15 bits

Figure 24-44. Data Write Message Format

### 24.9.2.2 Data Read Message

The data read message contains the data read value and the address of the target location, relative to the previous data trace message.

The data read message has the following format:

| [6 bits]             | [1 to 25 bits]   | [8, 16, 24, or 32 bits] |
|----------------------|------------------|-------------------------|
| TCODE (6)            | Relative Address | Data Value              |
| Max Length = 63 bits |                  |                         |
| Min Length = 15 bits |                  |                         |

**Figure 24-45. Data Read Message Format**

### 24.9.2.3 Data Trace Synchronization Messages

A data trace synchronization message shall be transmitted via the auxiliary port (provided data trace is enabled) for the following conditions:

- Initial data trace message upon exit of any system reset will be a synchronization message.
- Upon exit of sleep, deep-sleep and low power down mode, the first data trace message will be a synchronization message.
- Initial data trace message upon exit of background debug mode. Upon exiting BDM, the next data trace message will be a synchronization message.
- When data trace is enabled, the first data trace message will be a synchronization message.
- After 255 data trace messages have been queued without synchronization, the next data trace message will be a synchronization message.
- Upon assertion of an event In (EVTI) signal. If the READI module is not disabled at reset, when EVTI asserts, if the EC field is 0b00 in the DC register, the next data trace message will be a synchronization message.
- Upon occurrence of a watchpoint, the next data trace message will be a synchronization message.
- Occurrence of queue overrun. A data trace overrun error occurs when a trace message cannot be queued due to the queue being full (provided data trace is enabled). This causes the message queue to be flushed, and an error message is placed as the first message in the queue. The error code within the error message indicates that program/data/ownership trace overrun has occurred. The next data trace message will be a synchronization message.

Data trace synchronization messages provide the full address (without leading zeros) and ensure that development tools fully synchronize with data trace regularly. Synchronization messages provide a reference address for subsequent DTMs, in which only the unique portion of the data trace address is transmitted.

Data trace synchronization messages are of two types:

- Data write
- Data read

### 24.9.2.4 Data Write Synchronization Message

The data write synchronization message has the following format:

|            |                    |                     |                     |
|------------|--------------------|---------------------|---------------------|
| [6 bits]   | [1 bit]            | [1 to 25 bits]      | [8, 16, or 32 bits] |
| TCODE (13) | Messages Cancelled | Full target address | Data Value          |

Max Length = 64 bits

Min Length = 16 bits

**Figure 24-46. Data Write Synchronization Message Format**

### 24.9.2.5 Data Read Synchronization Messaging

The data read synchronization message has the following format:

|            |                    |                     |                     |
|------------|--------------------|---------------------|---------------------|
| [6 bits]   | [1 bit]            | [1 to 25 bits]      | [8, 16, or 32 bits] |
| TCODE (14) | Messages Cancelled | Full target address | Data Value          |

Max Length = 64 bits

Min Length = 16 bits

**Figure 24-47. Data Read Synchronization Message Format**

### 24.9.2.6 Relative Addressing

Refer to [Section 24.9.2.6, “Relative Addressing,”](#) for further details.

## 24.9.3 Queue Overflow Data Trace Error Message

A program/data/ownership trace overrun error or data trace error occurs when a trace message cannot be queued due to the queue being full, provided data trace is enabled.

The overrun error causes the message queue to be flushed, and an error message to be queued. The error code within the error message indicates that a program/data/ownership trace overrun error has occurred. The next DTM will be a synchronization message. Refer to [Table 24-20](#).

The error message has the following format:

|           |                                                     |
|-----------|-----------------------------------------------------|
| [6 bits]  | [5 bits]                                            |
| TCODE (8) | Error Code (0b0 0000, 0b0 0001, 0b0 0010, 0b0 0111) |

Length = 11 bits

**Figure 24-48. Error Message (Queue Overflow) Format**

## 24.9.4 Data Trace Operation

Data trace is performed by snooping the L-bus for read or write cycles. Data trace functions are enabled by setting the appropriate fields in the DC register and the DTA registers. For details on field configuration,

refer to [Section 24.6.1.4, “Development Control Register \(DC\),”](#) and [Section 24.6.1.9, “Data Trace Attributes 1 and 2 Registers \(DTA1 and DTA2\),”](#) respectively.

Data trace flow is depicted in [Figure 24-49](#).

**Figure 24-49. Data Trace Flow Diagram for Non-Pipelined Access**

## 24.9.5 Data Trace Windowing

Data trace windowing is achieved via the address range within the DTEA and the DTSA fields of the DTA registers. All L-bus accesses which fall within these two address ranges, provided the address ranges are enabled in either DTA register, are candidates to be transmitted. Data read and/or data write trace may be enabled via the TA field of the data trace attributes registers (DTA).

### NOTE

Data trace ranges are word aligned. Therefore, the address range fields (DTEA and DTSA) of the DTA registers are only 23 bits wide and, as such, should be assigned by the tool with the 23 most significant bits of the intended 25-bit range address, i.e. the 2 LSB of the address are not used.)

### NOTE

The off-core MPC500 special purpose register (SPR) map cannot be distinguished from the normal memory map accesses via the defined address range control. If data trace ranges are set up such that the off-core MPC500 SPR map falls within active ranges, then accesses to these off-core MPC500 SPRs will be traced, and the messages will not be distinguishable from accesses to normal memory map space. Off-core MPC500 SPRs typically exist in the 8-Kbyte – 16-Kbyte lowest memory block (0x2000 - 0x3FF0). If data or peripherals are mapped to this space, load/stores to MPC500 SPRs will be indistinguishable from data or peripheral accesses.

## 24.9.6 Special L-Bus Cases

Special L-bus cases are handled as described in [Table 24-30](#).

**Table 24-30. Special L-Bus Case Handling**

| Special Case                                       | Action                         |
|----------------------------------------------------|--------------------------------|
| L-bus Cycle Aborted                                | Cycle ignored                  |
| L-bus Cycle with data error                        | Message discarded              |
| L-bus Cycle terminated due to address error        | Cycle ignored                  |
| L-bus Cycle completed without error                | Cycle captured and transmitted |
| L-bus Cycle initiated by READI (Read/Write Access) | Cycle ignored                  |
| L-bus Cycle is an instruction fetch                | Cycle ignored                  |
| Data Storage Interrupt                             | Cycle ignored                  |
| System Reset                                       | Cycle ignored                  |

## 24.9.7 Data Trace Queuing

For queuing program trace, data trace, and ownership trace messages, READI implements a queue 32 messages deep (The queue is 16 messages deep on some versions; refer to device errata). Messages that enter the queue are transmitted via the output auxiliary port in the order in which they are queued.

## NOTE

If multiple trace messages need to be queued at the same time, program trace messages have a higher priority for queue entry than data trace messages, unless the data trace buffers are full, in which case the data trace messages are given temporary higher priority than the program trace messages.

## 24.9.8 Throughput and Latency

### 24.9.8.1 Assumptions for Throughput Analysis

- All accesses are data trace only
- 56-MHz operation
- Output signals are always free (not in middle of transmission) when requested
- Relative Address field for data trace messages is 20 bits
- Data field for data trace messages is 32 bits
- One idle clock between data trace messages

### 24.9.8.2 Throughput Calculations

The data (read or write) trace message is 58 bits (6 [TCODE] + 20 [Relative address] + 32 [Data]).

Data trace messages are transmitted out via the MDO signals. Hence it will take eight clocks (58 bits/8 MDO signals) to send a message. There will be one idle clock before the next data trace message can be sent.

At 56 MHz, it will take 161ns  $((8+1) \times 17.8)$  to transmit the message.

Therefore, the average number of data trace messages that can be transmitted out is 6.2 million (1/161ns) per second, or 24.8 million bytes of read/write data per second.

## 24.9.9 Data Timing Diagrams

Figure 24-50. Data Write Message

**Figure 24-51. Data Read Message**

**Figure 24-52. Data Write Synchronization Message**

**Figure 24-53. Data Read Synchronization Message**

**Figure 24-54. Error Message (Program/Data/Ownership Trace Overrun)**

## 24.10 Read/Write Access

The read/write access feature allows access to internal memory-mapped space via the auxiliary port. Read/write mechanism supports single and block, reads and writes.

### 24.10.1 Functional Description

The READI module is capable of bus mastership on the L-bus and for setting up and reading data and status.

All accesses are setup and initiated to the read/write access register (RWA) and upload/download information register (UDI) via the four auxiliary access public messages: device ready for upload/download, upload request (tool requests information), download request (tool provides information), upload/download information (device/tool provides information).

Read/write access features are enabled by setting the appropriate fields in the RWA register. For details on field configuration, refer to [Section 24.6.1.7, “Read/Write Access Register \(RWA\).”](#)

The functional flow for read/write access to memory-mapped locations and MPC500 registers is depicted in [Figure 24-59](#).

**Figure 24-55. Target Ready Message**

**Figure 24-56. Read Register Message**

Max Length = 94 bits  
Min Length = 22 bits

**Figure 24-57. Write Register Message**

Max Length = 86 bits  
Min Length = 14 bits

**Figure 24-58. Read/Write Response Message**

Figure 24-59. Read/Write Access Flow Diagram

## 24.10.2 Write Operation to Memory-Mapped Locations and SPR Registers

### 24.10.2.1 Single Write Operation

For a single write access to memory-mapped locations and SPR registers, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting download request public message (TCODE=18).

2. The download request public message contains:
  - a) TCODE(18)
  - b) Access opcode 0xF which signals that subsequent data needs to be stored in the RWA register.
  - c) Configure the RWA register fields as follows:
    - Start/complete (1 to indicate start access) -> SC
    - Read/write address (write address) -> RWAD
    - Read/write (1 to indicate a write access) -> RW
    - Word size (32 bits, 16 bits, 8 bits) -> SZ
    - Write data (write data) -> WD
    - Privilege (user data/instruction, supervisor data/instruction) -> PRV
    - Map select (select memory map, 0b0 or 0b1) -> MAP
      - 0 = Normal memory access
      - 1 = Secondary memory map (SPR)
    - Access Count (0 to indicate single access) -> CNT
3. After completion of the write operation, the device ready for upload/download public message (TCODE=16) is transmitted to the tool indicating that the device is ready for next access.
4. The SC bit is cleared to indicate that the write access is complete.

### 24.10.2.2 Block Write Operation

For a block write access to memory-mapped locations, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting download request public message (TCODE = 18).
2. The download request public message contains:
  - a) TCODE(18)
  - b) Access opcode 0xF which signals that subsequent data needs to be stored in the RWA register.
  - c) Configure the RWA register fields as follows
    - Start/complete (1 to indicate start access) -> SC
    - Read/write address (starting write address of block) -> RWAD
    - Read/write (1 to indicate a write access) -> RW
    - Word size (32 bits, 16 bits, 8 bits) -> SZ
    - Write data (write data) -> WD
    - Privilege (user data/instruction, supervisor data/instruction) -> PRV
    - Map select (select memory map 0b0) -> MAP
    - Access count (non zero number to indicate size of block access) -> CNT
3. After completion of this write operation, the device ready for upload/download public message (TCODE = 16) is transmitted to the tool indicating that the device is ready for next access.

4. The specified address (stored in RWAD field) is incremented to the next word size and the number in the CNT field is decremented. The SC field is not cleared.
5. The tool transmits the next upload/download information public message (TCODE = 19).
6. The upload/download information public message contains:
  - a) TCODE(19)
  - b) Write data (write data -> UDI)
7. After the completion of this write operation, the device ready for upload/download public message (TCODE = 16) is transmitted to the tool indicating that the device is ready for next access.
8. The specified address (in RWAD field) is incremented to the next word size and the number in the CNT field is decremented. The SC field is not cleared.
9. Steps 5 through 8 are repeated until the count value in the CNT field of RWA register equals zero. The SC bit is cleared to indicate end of the block write access.

### NOTE

For downloading write data to the device for block write operation, the download request public message (TCODE = 18) should not be used to write subsequent data to the UDI register. Data written to the UDI register (via download request message, TCODE 18) is not used by the device for any read/write operation.

## 24.10.3 Read Operation to Memory-Mapped Locations and SPR Registers

### 24.10.3.1 Single Read Operation

For a single read access to memory-mapped locations and SPR registers, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting download request public message (TCODE = 18).
2. The download request public message contains:
  - a) TCODE(18)
  - b) Access opcode 0xF which signals that subsequent data needs to be stored in the RWA register.
  - c) Configure the RWA fields as follows:
    - Start/complete (1 to indicate start access) -> SC
    - Read/write address (read address) -> RWAD
    - Read/write (0 to indicate a read access) -> RW
    - Word size (32 bits, 16 bits, 8 bits) -> SZ
    - Write data (0xFFFFFFFF-> WD [don't care])
    - Privilege (user data/instruction, supervisor data/instruction) > PRV
    - Map select (select memory map, 00 or 01) -> MAP
    - Access count (0 to indicate single access) -> CNT
3. Data read from the specified address is stored in the UDI register.

4. Once the read access is completed, the upload/download information public message (TCODE = 19) is transmitted to the tool along with the data read from the UDI register. This message also indicates that the device is ready for next access.
5. The SC field in the RWA register is cleared.

### 24.10.3.2 Block Read Operation

For a block read access to memory-mapped locations and SPR registers, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting download request public message (TCODE = 18).
2. The download request public message contains:
  - a) TCODE(18)
  - b) Access opcode 0xF which signals that subsequent data needs to be stored in the RWA register.
  - c) Configure the RWA fields as follows:
    - Start/complete (1 to indicate start access) -> SC
    - Read/write address (starting read address of block) -> RWAD
    - Read/write (0 to indicate a read access) -> RW
    - Word size (32 bits, 16 bits, 8 bits) -> SZ
    - Write data (0xFFFFFFFF-> WD [don't care])
    - Privilege (user data/instruction, supervisor data/instruction) > PRV
    - Map select (select memory map 0b0) -> MAP
    - Access count (non-zero number to indicate block access) -> CNT
3. Data read from the specified address is stored in the UDI register.
4. After the completion of this read operation, the upload/download information public message (TCODE=19) is transmitted to the tool along with the data read from the UDI register. This message also indicates that the device is ready to perform the next read operation.
5. The specified address (in RWAD field) is incremented to the next word size and the number in the CNT field is decremented. The SC field is not cleared.
6. The data read from the new address is stored in the UDI register.
7. Steps 4 through 7 are repeated until the count value in the CNT field of RWA register equals zero. The SC bit is cleared to indicate end of the block read access.

## 24.10.4 Read/Write Access to Internal READI Registers

### 24.10.4.1 Write Operation

For a write access to internal READI registers, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting download request public message (TCODE = 18).

2. The download request public message contains:
  - a) TCODE(18)
  - b) Access opcode, which specifies the register where data needs to be written, (e.g., access opcode 0x14 indicates that DTA1 register is the target register).
  - c) Data to be written to the register.
3. After the data has been written to the targeted register, the device ready for upload/download public message (TCODE = 16) is transmitted to the tool indicating that the device is ready for next access.

#### 24.10.4.2 Read Operation

For a read access to internal READI registers, the following sequence of operations need to be performed via the auxiliary port:

1. The tool confirms that the device is ready before transmitting upload request public message (TCODE = 17).
2. The upload request public message contains:
  - a) TCODE(17)
  - b) Access opcode, which specifies the register where data needs to be read from, (for example, access opcode 0x14 indicates that DTA1 register is the target register).
3. The upload/download information public message (TCODE=19) is transmitted to the tool along with the data read from the targeted register indicating that the device is ready for next access.

#### 24.10.5 Error Handling

The READI module handles the various error conditions in the manner shown in the following sections.

##### 24.10.5.1 Access Alignment

The READI module will force address alignment based on the word size field (SZ) value. If the SZ field indicates word (32-bit) access, the least significant two bits of the read/write address field (RWAD) are ignored. If the SZ field indicates half-word (16-bit) access, the least significant bit of the read/write address field (RWAD) is ignored.

##### 24.10.5.2 L-Bus Address Error

An address error occurs on the L-bus when the address phase of a cycle is not completed normally. This could occur because of address not being valid or the address map not being valid. In such cases:

1. The access is terminated without retrying.
2. The SC bit of the RWA is reset. Block accesses do not continue.
3. The error message (TCODE = 8) is transmitted (error code 0b00011). Refer to [Table 24-20](#).

##### 24.10.5.3 L-Bus Data Error

L-bus data error is signalled due to:

- L-bus data phase error.
- U-bus address phase error (for a L-bus to U-bus cycle).
- U-bus data phase error (for a L-bus to U-bus cycle).

L-bus data error conditions are signalled along with the transfer acknowledge for the access. L-bus data error conditions may occur because of privilege violations, access to protected memory, etc. In such cases, for a read access, the ERR bit of the UDI is set, and the DV bit in the UDI is reset at the termination of the access. For a write access, an error public message (TCODE = 8) is transmitted (error code 0b00011).

## 24.10.6 Exception Sequences

The following cases are defined for sequences of the read/write protocol that differ from those described in the above sections:

1. If the SC bit is set to start READI read/write accesses, without valid values in the RWAD, then an L-bus address error may occur, which is handled as described above.
2. If a block access is in progress with all the cycles not yet completed, and the RWA is written to again, (with or without modifications), then the block access is terminated at the boundary of the nearest completed access. The resulting data is discarded and not written to the UDI. If a new access has been programmed in the RWA register, then that access will start once the controller has recovered.
3. When a block access is in progress with all the cycles not yet completed, writing the SC bit to 0 in RWA register will terminate the block access and device will send out device ready for upload/download message.
4. If a any type (single/block) of access is in progress with the cycles not yet completed, and system reset occurs, the device will send out an error message. The access will be terminated and the SC bit will be reset. Refer to [Table 24-20](#).
5. If any type of (single/block) of access is requested while system is in reset, the device will send out an error message. The access will not be started and the SC bit will be reset.

## 24.10.7 Secure Mode

For details refer to [Section 24.2.2, “Security.”](#)

## 24.10.8 Error Messages

### 24.10.8.1 Read/Write Access Error

An error message is sent out when an L-bus access error or data error on a write access occurs. The error code within the error message indicates that an L-bus address or L-bus data error occurred. For other error handling, see [Section 24.10.5, “Error Handling.”](#) For a list of error codes, refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-60. Error Message (Read/Write Access Error) Format**

### 24.10.8.2 Invalid Message

An error message is sent out when an invalid message is received by READI. The error code within the error message indicates that an invalid TCODE was detected in the auxiliary input messages by the signal input formatter. Refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-61. Error Message (Invalid Message) Format**

#### NOTE

If the TCODE is valid, then READI will expect that the correct number of packets have been received and no further checking will be performed. If the number of packets received by READI is not correct, READI response is not deterministic.

### 24.10.8.3 Invalid Access Opcode

An error message is sent out when an invalid access opcode is received by READI. The error code within the error message indicates that an invalid access opcode was detected in the auxiliary input messages by the signal input formatter. Refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-62. Error Message (Invalid Access Opcode) Format**

## 24.10.9 Faster Read/Write Accesses with Default Attributes

Read/write access throughput may be increased by taking advantage of the default settings of the RWA register, and truncating the least significant zero bits of the download request message. For example, to read a word from the default memory map, with default attributes, a download request message that selects

the RWA register, and transmits the SC, RWAD, RW fields only is sufficient. This message will contain 41 bits instead of the 94 bits for writing the full contents of the RWA register. See [Table 24-11](#) and [Section 24.6.4, “Partial Register Updates,”](#) for RWAR and partial register update details respectively.

### NOTE

The last data bit transmitted in the download request message (TCODE 18) will always be the MSB of the register referenced by the opcode (SC field in the case of the RWA register).

## 24.10.10 Throughput and Latency

Throughput analysis has been performed for various read/write access cases such as single write, block write, single byte read, single word read, block byte read, block word read accesses to memory-mapped locations. Data is presented for the two cases when the RWA register is written partially and completely.

### 24.10.10.1 Assumptions for Throughput Analysis

- All accesses are single read accesses only.
- MCKI running at 28 MHz.
- MCKO running at 56 MHz.
- 56-MHz internal operation.
- Five clock internal L-bus access (read)
- Output signals always free (not in middle of transmission) when requested.
- One idle clock between read messages.
- No delay from tool in responding — tool keeps up with READI port.

**Table 24-31. Throughput Comparison for FPM and RPM MDO/MDI Configurations**

| Access Type                                                                                                                          | Reduced Port Mode<br>2 MDO / 1 MDI pins |                        | Full Port Mode<br>8 MDO / 2 MDI pins |                        |

**Figure 24-69. Error Message (Invalid Access Opcode)**

## 24.12 Watchpoint Support

This section details the watchpoint support features of the READI module.

The READI module provides watchpoint messaging via the auxiliary port, as defined by the IEEE-ISTO 5001-1999.

READI is not compliant with all the breakpoint/watchpoint requirements defined in the IEEE-ISTO 5001 standard. Watchpoint trigger and breakpoint/watchpoint control registers are not implemented.

Watchpoint setting via READI can only be done using the BDM protocol.

### 24.12.1 Watchpoint Messaging

The READI module provides watchpoint messaging using IEEE-ISTO 5001-1999 defined public messages. The watchpoint status signals from the RCPU are snooped, and when watchpoints occur, a message is sent to the signal output formatter to be messaged out (the general message queue is bypassed to prevent watchpoint messages from being cancelled in the event of a queue overflow). The watchpoint

message has the second highest priority. Refer to [Section 24.7.3, “Message Priority,”](#) for further details on message priorities. The watchpoint message contains the watchpoint code which indicates all the unique watchpoints have occurred since the last watchpoint message. If duplicate watchpoints occur before the watchpoint message is sent out, a watchpoint overrun message is generated. The watchpoint source field will indicate which watchpoints occurred.

The watchpoint message has the following format:

**Figure 24-70. Watchpoint Message Format**

### 24.12.1.1 Watchpoint Source Field

The watchpoint source field is outlined in [Table 24-32](#).

**Table 24-32. Watchpoint Source**

| Watchpoint Source | Description                   |
|-------------------|-------------------------------|
| 0bXXXXX1          | First L-bus watchpoint (LW0)  |
| 0bXXXX1X          | Second L-bus watchpoint (LW1) |
| 0bXXX1XX          | First I-bus watchpoint (IW0)  |
| 0bXX1XXX          | Second I-bus watchpoint (IW1) |
| 0bX1XXXX          | Third I-bus watchpoint (IW2)  |
| 0b1XXXXX          | Fourth I-bus watchpoint (IW3) |

### 24.12.2 Watchpoint Overrun Error Message

A watchpoint overrun error occurs when the same watchpoint occurs multiple times before the first occurrence of that watchpoint has been messaged out. The watchpoint message (which has information of all the watchpoints that occurred prior to the detection of the same watchpoint occurring multiple times) will be sent before the error message can be sent.

The overrun error causes further watchpoint occurrences to be ignored, until the error message has been sent. The error code within the error message indicates that a watchpoint overrun error has occurred. Refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-71. Error Message (Watchpoint Overrun) Format**

### 24.12.3 Synchronization

Upon occurrence of a watchpoint, the next program and data trace message will be a synchronization message (provided program and data trace are enabled).

### 24.12.4 Watchpoint Timing Diagrams

Figure 24-72. Watchpoint Message

Figure 24-73. Error Message (Watchpoint Overrun)

### 24.13 Ownership Trace

This section details the ownership trace support features of the READI module.

Ownership trace provides a macroscopic view, such as task flow reconstruction, when debugging software written in a high level (or object-oriented) language. It offers the highest level of abstraction for tracking operating system software execution. This is especially useful when the developer is not interested in debugging at lower levels.

## 24.13.1 Ownership Trace Messaging

Ownership trace information is messaged via the auxiliary port using an ownership trace message (OTM). The ownership trace register (OT), which can be accessed via auxiliary port, is updated by the operating system software to provide task/process ID information. When new information is updated in the register by the embedded processor, it is messaged out via the auxiliary port, allowing development tools to trace ownership flow.

Ownership trace information is messaged out in the following format:

**Figure 24-74. Ownership Trace Message Format**

## 24.13.2 Queue Overflow Ownership Trace Error Message

A program/data/ownership trace overrun error occurs when a trace message cannot be queued due to the queue being full, provided ownership trace is enabled.

The overrun error causes the message queue to be flushed, and a error message to be queued. The error code within the error message indicates that a program/data/ownership trace overrun error has occurred. Refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-75. Error Message Format**

### 24.13.2.1 OTM Flow

Ownership trace messages are generated when the operating system (privileged supervisor task) writes to the memory-mapped ownership trace register.

The following flow describes the OTM process.

1. The OT register is a memory-mapped register, whose address is located in the UBA. The OT register address can be read from the UBA register by the IEEE-ISTO 5001 tool.
2. Only privileged writes (byte/half word or word) initiated by the RCPU to the OT register that terminate normally are valid. The data value (word) written into the register is formed into the ownership trace message that is queued to be transmitted.
3. OT register reads and non-privileged OT register writes, or writes initiated by any source other than the RCPU, do not cause ownership trace messages to be transmitted by the READI module.

### 24.13.2.2 OTM Queueing

READI implements a queue 32 messages deep for program trace, data trace, and ownership trace messages. Messages that enter the queue are transmitted via the output auxiliary port in the order in which they are queued.

#### NOTE

If multiple trace messages need to be queued at the same time, ownership trace messages will have the lowest priority.

### 24.13.3 OTM Timing Diagrams

Figure 24-76. Ownership Trace Message

Figure 24-77. Error Message (Program/Data/Ownership Trace Overrun)

## 24.14 RCPU Development Access

This section details the RCPU development access support features of the READI module.

The READI development port provides a full duplex serial interface for accessing existing RCPU user register and development features including BDM (background debug mode).

RCPU development access can be achieved either via the READI signals or the BDM signals on the MCU. The access method is determined during READI module configuration. Figure 24-78 shows how READI and BDM signals are multiplexed for RCPU development access.

When the READI module is configured for RCPU development access, IEEE-ISTO 5001 compliant vendor-defined messages are used for transmission of data in and out of the MCU.

### NOTE

On the MPC561/MPC563 the BDM signals are shared with the READI signals. Therefore BDM access is limited to access via the Nexus vendor-defined development support messages.

Figure 24-78. RCPU Development Access Multiplexing between READI and BDM Signals

## 24.14.1 RCPU Development Access Messaging

The following RCPU development access messages are used for handshaking between the device and the tool — DSDI data message, DSDO data message, and BDM status message.

### 24.14.1.1 DSDI Message

The DSDI message is used by the tool to download information to the RCPU.

The DSDI data field has a 3-bit status header followed by 7 or 32 bits of data/instruction, depending on the RCPU development port mode.

The DSDI message has the following format:

**Figure 24-79. DSDI Message Format**

### NOTE

When sending in a DSDI data message, the DSDI data should contain the control and status bits (start, mode, control), followed by the 7 or 32-bit CPU instruction/data or trap enable, MSB first. See [Figure 24-85](#) for DSDI data message transmission sequence.

## 24.14.1.2 DSDO Message

The DSDO message is used by the device to upload information from the RCPU.

The DSDO data field has a 3-bit status header followed by 7 or 32 bits of data/instruction, depending on the RCPU development port mode.

The three status bits in the DSDO data indicates if the device is ready to receive the next message from the tool.

The DSDO message has the following format:

**Figure 24-80. DSDO Message Format**

### NOTE

The DSDO data received will contain the control and status bits and data from the CPU, MSB first. See [Figure 24-85](#) for DSDO data message transmission sequence.

## 24.14.1.3 BDM Status Message

BDM status message is generated by the device to let the tool know about the status of debug mode.

BDM status message (with BDM status field equal to 0b1) is sent when the RCPU is in debug mode and the device is ready to receive debug mode messages.

BDM status message (with BDM status field equal to 0b0) is sent out when the device exits BDM mode and RCPU is in normal operating mode.

The BDM status message has the following format:

**Figure 24-81. BDM Status Message Format**

#### 24.14.1.4 Error Message (Invalid Message)

An error message is sent out when an invalid message is received by READI. The error code within the error message indicates that an invalid TCODE was detected in the auxiliary input messages by the signal input formatter. Refer to [Table 24-20](#).

The error message has the following format:

**Figure 24-82. Error Message (Invalid Message) Format**

### 24.14.2 RCPU Development Access Operation

The RCPU development access can be achieved either via the READI signals or the BDM signals.

To enable RCPU development access via the READI signals, the tool has to configure the DC register during the READI reset ( $\overline{\text{RSTI}}$ ). Once the READI module takes the control of RCPU development access, the protocol for transmission of development serial data in (DSDI) and out (DSDO) is performed through the IEEE-ISTO 5001-1999 compliant vendor-defined messages.

After enabling RCPU development access via the READI signals, the READI module can enable debug mode and enter debug mode. When debug mode is enabled and entered, READI sends a BDM status message (BDM status field equal to 0b1) to the development tool indicating that the RCPU has entered debug mode and is now expecting instructions from the READI signals.

The development tool then uses the DSDI Data Message to send in the serial transmission data to READI. Data is transmitted to the tool using the DSDO data message.

This process continues until the RCPU exits debug mode and READI sends the BDM status message (BDM status field equal to 0b0) indicating debug mode exit.

#### NOTE

Only after the DSDO data message is sent out should another DSDI data message be sent in.

Synchronous self-clocked mode is selected by READI for RCPU development access. In this mode, the internal transmission between READI and the USIU is performed at system frequency.

When the RCPU is in debug mode, program trace is not allowed. If program trace is enabled, a program trace synchronization message is generated when debug mode exits.

When the RCPU is in debug mode, data trace and  $R/\overline{W}$  access are allowed.

The flow chart in [Figure 24-83](#) shows RCPU development access configuration via READI. The modes of RCPU development access via READI are described below. Allowed modes are also summarized in [Table 24-8](#) of [Section 24.14.2.4](#), “RCPU Development Access Flow Diagram.”

### 24.14.2.1 Enabling RCPU Development Access Via READI Signals

Reset sequencing is done by the tool to initialize the READI signals and registers by asserting  $\overline{RSTI}$  (the device sends out the device ID message after the  $\overline{RSTI}$  negation). System reset is held by the tool until the READI module is reset and initialized with desired RCPU development access setting.

#### NOTE

The READI module will ignore any incoming DSDI data messages when the module is not configured for RCPU development access.

### 24.14.2.2 Entering Background Debug Mode (BDM) Via READI Signals

There are three ways to enter debug mode (provided debug mode has been enabled):

1. Enter debug mode (halted state) out-of-system reset through READI module configuration. This is displayed in [Figure 24-84](#).
2. Enter debug mode by downloading breakpoint instructions through RCPU development access when in non-debug (running) mode.
3. Enter debug mode if an exception or interrupt occurs.

When entering debug mode following an exception/breakpoint, the RCPU signals  $VFLS[0:1]$  are equal to 0b11. This causes READI to send a BDM status message to the tool indicating that the RCPU has entered debug mode and is now expecting instructions from the READI signals.

Debug mode enabling through READI and entering debug mode out of system reset is done by setting the following bits in the DC register (DME=0b1, DOR=0b1) during system reset. Debug mode entry causes RCPU to halt.

### 24.14.2.3 Non-Debug Mode Access of RCPU Development Access

The RCPU development access can be also be used while the RCPU is not halted (in debug mode). This feature is used to send in breakpoints or synchronization events to the RCPU. Please refer to [Chapter 23](#), “Development Support” for further details.

Non-debug mode access of RCPU development can be achieved by configuring the READI module to take control of RCPU development access during module configuration of the DC register (DME=0b0, DOR=0bx).

## 24.14.2.4 RCPU Development Access Flow Diagram

Figure 24-83 has flow diagram describing how the RCPU development access can be achieved via READI signals.

Figure 24-83. RCPU Development Access Flow Diagram

### 24.14.3 Throughput

The tool can send a DSDI data message into device upon the receipt of a DSDO data message as soon as the tool decodes the first two status bits of the DSDO data message just received and confirms valid data from the RCPU.

An example throughput analysis is performed with the following assumptions:

- READI configuration of RCPU development access and debug mode is already entered through READI
- The module is configured for reduced port mode
- MCKI running at 28 MHz
- MCKO running at 56 MHz
- 56-MHz internal operation
- READI auxiliary input and output signals are free (not in middle of transmission)
- No delay from tool in responding — tool keeps up with READI port
- Tool reads the complete DSDO data message before shifting in DSDI data message
- 10 clocks estimated to format and encode/decode DSDI data and DSDO data messages within READI

The DSDI data message is 41 bits (six bits of TCODE and 35 bits of DSDI data.). It takes 41 clocks (41 bits / 1 MDI signals) to shift in the DSDI data message. It is estimated that READI will take approximately 10 clocks to decode the DSDI data message. After the message has been decoded, READI will take 35 clocks to serially shift in the 35 bits of DSDI data to the RCPU development port. Hence, it takes a total of 86 clocks (41 + 10 + 35) to decode and shift in DSDI data from the tool to the RCPU development port.

At 28 MHz, it translates to 3079 ns ( $35.8 \times 81$ ) to decode and shift in DSDI data to RCPU development port

As DSDI bits are shifted into the RCPU development register, DSDO bits are shifted out from the same RCPU development register (DPDR) and these are captured by READI.

It is estimated that READI will take approximately 10 clocks to encode the DSDO data. The DSDO message is 41 bits (6 bits of TCODE and 35 bits of DSDO data). It will take 21 clocks (41 bits / 2 MDO signals) for READI to transmit this message. Hence, it will take a total of 31 clocks (10 + 21) to encode the DSDO data message and shift out the DSDO data message to the tool.

At 56 MHz, it will take 552 ns ( $17.8 \times 31$ ) to encode and shift out DSDO data to the tool.

Thus, it will take 3631 ns (3079 + 552) for one complete DSDI data and DSDO data messaging cycle.

### 24.14.4 Development Access Timing Diagrams

Figure 24-84 shows the timing diagram of RCPU development access and entering debug mode out-of-system reset through READI.

Figure 24-84. RCPU Development Access Timing Diagram — Debug Mode Entry Out-of-Reset

Figure 24-85 shows the transmission sequence of DSDI/DSDO data messages.

Figure 24-85. Transmission Sequence of DSDx Data Messages

DSDI message fields of the development port access message are explained in [Table 24-33](#).

**Table 24-33. Development Port Access: DSDI Field**

| Header |      |         | Data                         |                | Function                                      |
|--------|------|---------|------------------------------|----------------|-----------------------------------------------|
| Start  | Mode | Control | Instruction / Data (32 Bits) |                |                                               |
|        |      |         | Bits 0:6                     | Bits 7:31      |                                               |
| 1      | 0    | 0       | CPU Instruction              |                | Transfer Instruction to CPU                   |
| 1      | 0    | 1       | CPU Data                     |                | Transfer Data to CPU                          |
| 1      | 1    | 0       | Trap enable                  | Does not exist | Transfer data to Trap Enable Control Register |
| 1      | 1    | 1       | 0011111                      | Does not exist | Negate breakpoint requests to the CPU.        |
| 1      | 1    | 1       | 0                            | Does not exist | NOP                                           |

DSDO message fields of the development port access message are explained in [Table 24-34](#).

**Table 24-34. Development Port Access: DSDO Field**

| Header |              |   | Data                       |                                             |                                              | Function            |

## 24.15 Power Management

This section details the power management features of the READI module.

The READI module is a development interface, and is not expected to function under normal (non-development) conditions. Therefore power management is required to reduce and minimize power consumption during normal operation of the part.

### 24.15.1 Functional Description

The following are the candidates for power management:

Table 24-35. Power Management Mechanism Overview

| Feature                                   | Power Saving Mechanism                                                                                                                                                                                |
|-------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Disabled Mode                             | If $\overline{\text{EVTI}}$ is negated at negation of $\overline{\text{RSTI}}$ , the READI module will be disabled. No trace output will be provided, and output auxiliary port will be three-stated. |
| Sleep, Deep-Sleep and Low Power-Down Mode | All outputs will be held static.                                                                                                                                                                      |
| READI Reset ( $\overline{\text{RSTI}}$ )  | Output auxiliary signals will be three-stated.                                                                                                                                                        |

### 24.15.2 Low Power Modes

When the MCU is in sleep, deep-sleep, or low power-down mode, all internal clocks on the MCU are shut down, including the MCKO. The  $\overline{\text{MSEO}}$  signal will be held negated.

Low power mode entry for the MCU will be held off until the READI module has transmitted all existing messages (in the queues and transmit buffers). During this time, input messages from the development tool are ignored.

Upon restoration of clocks in normal mode, program and data traces will be synchronized, if enabled.

## Chapter 25

# IEEE 1149.1-Compliant Interface (JTAG)

The chip design includes user-accessible test logic that is compatible with the IEEE 1149.1-1994 Standard Test Access Port and Boundary Scan Architecture. The implementation supports circuit-board test strategies based on this standard. An overview of the pins requirement on JTAG is shown in [Figure 25-1](#).

Figure 25-1. Pin Requirement on JTAG

### 25.1 IEEE 1149.1 Test Access Port

The MPC561/MPC563 provides a dedicated user-accessible test access port (TAP) that is compatible with the IEEE 1149.1 Standard Test Access Port and Boundary Scan Architecture in all but two areas listed below. Problems associated with testing high density circuit boards have led to development of this proposed standard under the sponsorship of the Test Technology Committee of IEEE and the Joint Test Action Group (JTAG). The MPC561/MPC563 implementation supports circuit-board test strategies based on this standard.

IEEE1149.1 Compatibility Exceptions:

- The MPC561/MPC563 enters JTAG mode by going through a standard device reset sequence with the JCOMP signal asserted high during PORESET negation. Once JTAG has been entered, the MPC561/MPC563 remains in JTAG mode until another reset sequence is applied to exit JTAG mode, or the device is powered down.
- The JTAG output port, TDO, is configured with a weak pull-up until reset negates or the driver is disabled.

The TAP consists of five dedicated signal pins, a 16-state TAP controller, and two test data registers. A boundary scan register links all device signal pins into a single shift register. The test logic implemented utilizes static logic design. The MPC561/MPC563 implementation provides the capability to:

1. Perform boundary scan operations to test circuit-board electrical continuity.
2. Bypass the MPC561/MPC563 for a given circuit-board test by effectively reducing the boundary scan register to a single cell.
3. Sample the MPC561/MPC563 system pins during operation and transparently shift out the result in the boundary scan register.
4. Disable the output drive to pins during circuit-board testing.

#### NOTE

Certain precautions must be observed to ensure that the IEEE 1149-like test logic does not interfere with nontest operation. JCOMP must be low prior to  $\overline{\text{PORESET}}$  assertion after low power mode exits, otherwise an unknown state will occur.

### 25.1.1 Overview

An overview of the MPC561/MPC563 scan chain implementation is shown in [Figure 25-2](#). The MPC561/MPC563 implementation includes a TAP controller, a 4-bit instruction register, and two test registers (a one-bit bypass register and a 427-bit (MPC563) or 423-bit (MPC561) boundary scan register). This implementation includes a dedicated TAP consisting of the following signals:

- TCK — a test clock input to synchronize the test logic. (with an internal pull-down resistor)
- TMS — a test mode select input (with an internal pullup resistor) that is sampled on the rising edge of TCK to sequence the TAP controller's state machine.
- TDI — a test data input (with an internal pullup resistor) that is sampled on the rising edge of TCK.
- TDO — a three-state test data output that is actively driven in the shift-IR and shift-DR controller states. TDO changes on the falling edge of TCK. (This pin also has a weak pull-up that is active when output drivers are disabled, except during a HI-Z instruction).
- $\overline{\text{TRST}}$  — an asynchronous reset with an internal pull-up resistor that provides initialization of the TAP controller and other logic required by the standard. This input is multiplexed with the  $\overline{\text{PORESET}}$  signal.
- JCOMP — JTAG Compliancy – This signal provides JTAG IEEE1149.1 compatibility and selects between normal operation (low) and JTAG test mode (high).

#### NOTE

JTAG mode does not provide access to the internal MPC561/MPC563 circuitry. It allows access only to the input or output pad (periphery) circuitry.

Figure 25-2. Test Logic Block Diagram

## 25.1.2 Entering JTAG Mode

To enable JTAG on reset for board test JCOMP/ $\overline{\text{RSTI}}$  must be high on  $\overline{\text{PORESET}}$  rising edge as shown in Figure 25-3.

### NOTE

JTAG puts all output pins in fast slew rate mode. Enough current cannot be supplied to allow all the pins to be switched simultaneously, so this should be avoided.

Figure 25-3. JTAG Mode Selection

### 25.1.2.1 TAP Controller

The TAP controller is responsible for interpreting the sequence of logical values on the TMS signal. It is a synchronous state machine that controls the operation of the JTAG logic. The state machine is shown in Figure 25-4. The value shown adjacent to each arc represents the value of the TMS signal sampled on the rising edge of the TCK signal.

Figure 25-4. TAP Controller State Machine

### 25.1.2.2 Boundary Scan Register

The MPC561/MPC563 scan chain implementation has a 427-bit (MPC563) or 423-bit (MPC561) boundary scan register. This register contains bits for most device signals, clock pins and associated control signals. The XTAL, EXTAL and XFC pins are associated with analog signals and are not included in the boundary scan register. The PORESET, HRESET, and SRESET pins are also excluded from the boundary scan register.

The 520-bit boundary scan register can be connected between TDI and TDO by selecting the EXTEST or SAMPLE/PRELOAD instructions. This register is used to capturing signal pin data on the input pins, forcing fixed values on the output signal pins, and selecting the direction and drive characteristics (a logic value or high impedance) of the bidirectional and three-state signal pins.

The key to using the boundary scan register is knowing the boundary scan bit order and the pins that are associated with them. [Table 25-1](#) shows the bit order starting from the TDO output and going to the TDI input.

[Table 25-1](#) displays boundary scan bit definitions for the MPC561 and [Table 25-2](#) displays boundary scan bit definitions for the MPC563.

**Table 25-1. MPC561 Boundary Scan Bit Definition**

| BSDL Bit | Cell Type | Pin/Port Name | BSDL Function | Safe Value | Control Cell | Disable Value | Disable Result | Pin Function | Pad Type |
|----------|-----------|---------------|---------------|------------|--------------|---------------|----------------|--------------|----------|

Table 25-2. MPC563 Boundary Scan Bit Definition (continued)

| BSDL Bit | Cell Type | Pin/Port Name               | BSDL Function | Safe Value | Control Cell | Disable Value | Disable Result | Pin Function | Pad Type |
|----------|-----------|-----------------------------|---------------|------------|--------------|---------------|----------------|--------------|----------|
| 417      | BC_2      | *                           | controlr      | 0          |              |               |                |              |          |
| 418      | BC_7      | IRQ4_B_AT2_SGPIOC4          | bidir         | 0          | 417          | 0             | Z              | IO           | 26v5vs   |
| 419      | BC_2      | *                           | controlr      | 0          |              |               |                |              |          |
| 420      | BC_7      | IRQ3_B_KR_B_RETRY_B_SGPIOC3 | bidir         | 0          | 419          | 0             | Z              | IO           | 26v5vs   |
| 421      | BC_2      | *                           | internal      | 1          |              |               |                |              |          |
| 422      | BC_2      | IWP0_VFLS0                  | output2       | 1          |              |               |                | O            | 26v      |
| 423      | BC_2      | *                           | internal      | 1          |              |               |                |              |          |
| 424      | BC_2      | IWP1_VFLS1                  | output2       | 1          |              |               |                | O            | 26v      |
| 425      | BC_2      | *                           | controlr      | 0          |              |               |                |              |          |
| 426      | BC_7      | SGPIOC6_FRZ_PTR_B           | bidir         | 0          | 425          | 0             | Z              | IO           | 26v5vs   |

- Bi-state outputs (Pin Function = O) such as mdo\_2, and mdo\_3, are incorporated with general I/O pads hard-wired to keep output enable always on in system mode. The JTAG Control cell, indicated by the next lower bsd1 bit in the chain, is configured as an “internal” only cell to be held at a “1” value (always driving out) during JTAG testing.
- Some input-only cells made with generic I/O pads are configured with “internal” control cells to keep them always in input mode, such as epee, b0epee, and input pins that may be attached to analog references. Other input-only cells are configured as bidirectional for JTAG testing, to give the board-level ATPG tools the flexibility to use the pad as an input or output, depending on the network of other devices that the pin is connected too. If it is desired to restrict these pins to only act as receivers during JTAG mode, then these JTAG bsd1 entries can be converted as shown in the example below:
- This description allows ATPG tools to use a pin as a driver or receiver:

|     |      |               |          |   |     |   |   |   |     |
|-----|------|---------------|----------|---|-----|---|---|---|-----|
| 188 | BC_2 | *             | controlr | 0 |     |   |   |   |     |
| 189 | BC_7 | irq6_b_modck2 | bidir    | 0 | 188 | 0 | Z | I | 26v |

- A modification to restrict ATPG tools to use a functional input-only pin as an input receiver only:

|     |      |               |          |   |  |  |  |   |     |
|-----|------|---------------|----------|---|--|--|--|---|-----|
| 188 | BC_2 | *             | internal | 0 |  |  |  |   |     |
| 189 | BC_4 | irq6_b_modck2 | input    | X |  |  |  | I | 26v |

- The  $\overline{\text{PORESET}}$ ,  $\overline{\text{HRESET}}$ , and  $\overline{\text{SRESET}}$  pins are not part of the JTAG boundary scan chain. These pins are used in the reset configuration to enter JTAG. Board-level connections to them will not be testable with the EXTEST and CLAMP instructions. They do respond to the Hi-Z JTAG instruction for parametric testing purposes.
- The XTAL, EXTAL, and XFC pins are associated with analog signals and are excluded from the boundary scan chain.
- The READI module reset pin, rsti\_b, (bsd1 pin 517) is in the JTAG boundary scan chain, but must be kept at a “0” level during JTAG testing, (except for Hi-Z testing), due to system interactions. It is classified as a “linkage” pin, and its data and control cells are configured to advise ATPG tools to drive a “0” value in during JTAG testing.
- Pad type naming conventions:
  - 26 V – 2.6 V
  - 5 V – 5 V
  - s – slow
  - f – fast
  - h – high drive
  - a – analog input
  - i – input only
  - d – has direct connection to the pad (may be used for module test)

- r – resized cell instance

#### 9. Column Descriptions:

- Columns 1 through 8 are entries from the boundary-scan description from the BSDL file. The columns and formats for each of these entries are defined in the IEEE Std. 1149.1b-1994 Supplement to the IEEE Std. 1149.1-1990, IEEE Standard Test Access Port and Boundary-Scan Architecture document. Descriptions of these columns are described below:
- Column 1: Defines the bit's ordinal position in the boundary scan register. The shift register cell nearest TDO (i.e., first to be shifted in) is defined as bit 0; the last bit to be shifted in is 519.
- Column 2: References one of the three standard JTAG Cell Types (BC\_4, BC\_2, and BC\_7) that are used for this JTAG cell in the MPC561/MPC563. See the IEEE Std. 1149.1-1990, IEEE Standard Test Access Port and Boundary-Scan Architecture document for further description of these standard cell types.
- Column 3: Lists the pin name (also called the PortID) for all pin-related cells. For JTAG control cells or data cells that have been designated as "internal", an asterisk, is shown in this column.
- Column 4: Lists the BSDL pin function.
- Column 5: The "safe bit" column specifies the value that should be loaded into the capture (and update) flip-flop of a given cell when board-level test generation software might otherwise choose a value randomly.
- Column 6: The "control cell" column identifies the cell number of the control cell that is associated with this data cell, and can disable its output.
- Column 7: The "disable value" column gives the value that must be scanned into the control cell identified by the previous "control cell" (column 6) to disable the port named by the relevant portID.
- Column 8: The "disable result" column identifies a given signal value of the PortID if that signal can be disabled. The values shown specifies the condition of the driver of that signal when it is disabled.
- Column 9: The "pin function" column indicates the normal system pin directionality. (– Input Only Pin, O – Output Only Pin, I/O – Bidirectional I/O pin)
- Column 10: The pad type column describes relevant characteristics about each pad type. See the Pad Type Keys in Note 5 above.

### 25.1.3 Instruction Register

The MPC561/MPC563 JTAG implementation includes the public instructions (EXTEST, SAMPLE/PRELOAD, and BYPASS), and also supports the CLAMP instruction. One additional public instruction (HI-Z) provides the capability for disabling all device output drivers. The MPC561/MPC563 includes a 4-bit instruction register without parity consisting of a shift register with four parallel outputs. Data is transferred from the shift register to the parallel outputs during the update-IR controller state. The four bits are used to decode the five unique instructions listed in.

**Table 25-3. Instruction Decoding**

| Code |    |    |                 |                  |
|------|----|----|-----------------|------------------|
| B3   | B2 | B1 | B0 <sup>1</sup> | Instruction      |
| 0    | 0  | 0  | 0               | EXTEST           |
| 0    | 0  | 0  | 1               | SAMPLE/PRELOAD   |
| 0    | X  | 1  | X               | BYPASS           |
| 0    | 1  | 0  | 0               | HI-Z             |
| 0    | 1  | 0  | 1               | CLAMP and BYPASS |

<sup>1</sup> B0 (LSB) is shifted first

The parallel output of the instruction register is reset to all ones in the test-logic-reset controller state.

#### NOTE

This preset state is equivalent to the BYPASS instruction.

During the capture-IR controller state, the parallel inputs to the instruction shift register are loaded with the CLAMP command code.

### 25.1.3.1 EXTEST

The external test (EXTEST) instruction selects the 520-bit boundary scan register. EXTEST also asserts internal reset for the MPC561/MPC563 system logic to force a predictable beginning internal state while performing external boundary scan operations.

By using the TAP, the register is capable of:

- scanning user-defined values into the output buffers
- capturing values presented to input pins
- controlling the output drive of three-state output or bidirectional pins

### 25.1.3.2 SAMPLE/PRELOAD

The SAMPLE/PRELOAD instruction initializes the boundary scan register output cells prior to selection of EXTEST. This initialization ensures that known data will appear on the outputs when entering the EXTEST instruction. The SAMPLE/PRELOAD instruction also provides a means to obtain a snapshot of system data and control signals.

#### NOTE

Since there is no internal synchronization between the scan chain clock (TCK) and the system clock (CLKOUT), there must be provision of some form of external synchronization to achieve meaningful results.

### 25.1.3.3 BYPASS

The BYPASS instruction selects the single-bit bypass register as shown in [Figure 25-5](#). This creates a shift register path from TDI to the bypass register and, finally, to TDO, circumventing the 520-bit boundary scan register. This instruction is used to enhance test efficiency when a component other than the MPC561/MPC563 becomes the device under test.

**Figure 25-5. Bypass Register**

When the bypass register is selected by the current instruction, the shift register stage is set to a logic zero on the rising edge of TCK in the capture-DR controller state. Therefore, the first bit to be shifted out after selecting the bypass register will always be a logic zero.

### 25.1.3.4 CLAMP

The CLAMP instruction selects the single-bit bypass register as shown in [Figure 25-5](#), and the state of all signals driven from system output pins is completely defined by the data previously shifted into the boundary scan register (for example, using the SAMPLE/PRELOAD instruction).

### 25.1.4 HI-Z

The HI-Z instruction is provided as a manufacturer's optional public instruction to prevent having to backdrive the output pins during circuit-board testing. When HI-Z is invoked, all output drivers, including the two-state drivers, are turned off (i.e., high impedance). The instruction selects the bypass register.

## 25.2 MPC561/MPC563 Restrictions

The control afforded by the output enable signals using the boundary scan register and the EXTEST instruction requires a compatible circuit-board test environment to avoid device-destructive configurations. The user must avoid situations in which the MPC561/MPC563 output drivers are enabled into actively driven networks.

The MPC561/MPC563 features a low-power stop mode. The interaction of the scan chain interface with low-power stop mode is as follows:

1. The TAP controller must be in the test-logic-reset state to either enter or remain in the low-power stop mode. Leaving the TAP controller in the test-logic-reset state negates the ability to achieve low-power, but does not otherwise affect device functionality.
2. The TCK input is not blocked in low-power stop mode. To consume minimal power, the TCK input should be externally connected to  $V_{DD}$  or ground.
3. The TMS pin includes an on-chip pull-up resistor. In low-power stop mode, this pin should remain either unconnected or connected to VDD to achieve minimal power consumption. Note that for proper reset of the scan chain test logic, the best approach is to pull JCOMP low at power-on reset (PORESET).
4. JCOMP must be low prior to  $\overline{\text{PORESET}}$  assertion after low power mode exits otherwise an unknown state will occur.

### 25.2.1 Non-Scan Chain Operation

In non-scan chain operation, there are two constraints. First, the TCK input does not include an internal pull-up resistor and should not be left unconnected to preclude mid-level inputs. The second constraint is to ensure that the scan chain test logic is kept transparent to the system logic by forcing TAP into the test-logic-reset controller state, using either of two methods. Connecting pin JCOMP to logic 0 (or one of the reset pins), or TMS must be sampled as a logic one for five consecutive TCK rising edges. If then TMS either remains unconnected or is connected to  $V_{DD}$ , then the TAP controller cannot leave the test-logic-reset state, regardless of the state of TCK.

## 25.2.2 BSDL Description

The BSDL file for the MPC561/MPC563 can be found on the Freescale web site.

## Appendix A

### MPC562/MPC564 Compression Features

The MPC562/MPC564 contains a number of code compression features not found in the MPC561/MPC563 that function from the burst buffer controller module (BBC) module of the device.

The BBC's instruction code decompressor unit (ICDU) is responsible for on-line (previously compressed) instruction code decompression in the decompression on mode. The ICDU contains a 2-Kbyte RAM (DECGRAM) that is used for decompressor vocabulary table storage when compression is enabled or as general-purpose memory on the U-bus when compression is disabled.

#### NOTE

The code compression features of the MPC562/MPC564 are different than the code compression of the MPC556.

#### A.1 ICDU Key Features

The following are instruction code decompression unit key features:

- Instruction code on-line decompression is based on an “instruction class” algorithm.
- There is no need for address translation between compressed and non-compressed address spaces — ICDU provides the “next instruction address” to the RCPU.
- In most cases, instruction decompression takes one clock.
- Code decompression is pipelined:
  - No performance penalty during sequential program flow execution
  - Minimal performance penalty due to change of program flow execution
- Two operation modes are available: decompression on and decompression off. Switches between compressed and non-compressed user application software is possible.
- Adaptive vocabularies scheme is supported; each user application can have its own optimum vocabularies.

#### A.2 Class-Based Compression Model Main Principles

The operational model used by the MPC562/MPC564 is explained in the sections below.

##### A.2.1 Compression Model Features

- Implemented for MPC56x architecture
- Up to 50% instruction code size reduction
- No need for address translation tables

- No changes in the CPU architecture
- A compressor tool performs compression off-line in software using instruction class-based algorithms optimized for the MPC56x instruction set
- Decompression is done at run-time by special hardware
- Optimized for cache-less systems:
  - Highly effective in system solutions for a low-cache hit ratio environment and for systems with fast embedded program memory
  - Deterministic program execution
  - No performance penalty during sequential program flow execution
  - Minimal performance penalty due to change of program flow execution
- Switches between compressed and non-compressed user application sections is possible. (A compressed subroutine can call a non-compressed one and be called from non-compressed portions of the user application)
- Adaptive vocabularies, generated for a particular application
- Compressed address space is up to 1 Gbyte
- Branch displacement from its target:
  - Conditional branch displacement is up to 4 Kbytes
  - Unconditional branch displacement is up to 4 Mbytes

#### NOTE

Branch displacement is hardware limited. The compiler can enlarge the branch scope by creating branch chains.

### A.2.2 Model Limitations

No address arithmetic is allowed for instruction space because the address map changes during compression and no software tool can identify address arithmetic structures in the code. Address arithmetic for data tables is permitted since data space is not compressed. Only instruction space is compressed.

### A.2.3 Instruction Class-Based Compression Algorithm

The code compression algorithm is based on creating optimal vocabularies of frequently appearing RCPU RISC instructions or instruction halves and replacing these instructions with pointers to the vocabularies. The system contains several sets of vocabularies for different groups of instructions. These groups are referred to as classes.

Every instruction belongs to exactly one class. Compression of the instructions in a class may be in one of the following modes. Refer to [Figure A-1](#).

1. Compression of the whole instruction into one vocabulary pointer
2. Compression of each half of the instruction into a different vocabulary

3. Compression of one of the instruction's halves into a vocabulary pointer and bypass of the other half. A bypassed field is one for which non-compressed data (16-bit halfword or 32-bit word) is placed in the compressed code. After compression is defined, the non-compressed data field is defined in the class.
4. Bypass of the whole instruction. No compression is permitted.

**Figure A-1. Instruction Compression Alternatives**

A 4-bit class identifier is added to the beginning of each compressed instruction to supply class identification during decompression. Compressed and bypass field lengths may vary. (A fully bypassed instruction, including its 4-bit class identifier, is 36 bits.)

The compressed instruction is guaranteed to start on an even bit. Thus, four bits are needed to find the starting location of the instruction inside a memory word. The instruction address in decompression on mode consists of a 28-bit word address (1 Gbyte of address space) and a 4-bit instruction pointer (IP). See [Figure A-2](#).

Figure A-2. Addressing Instructions with Compressed Address

## A.2.4 Compressed Address Generation with Direct Branches

During the compression process, compressed instructions change their location in the memory and are not word aligned. Displacement fields in the direct branch instructions have to be updated by the compression tool to make compressed instruction addressing possible. Four LSB bits of the displacement immediate field (LI or BD) in the compressed direct branch instructions are used for bit addressing in the 32-bit memory word. The remaining bits of the fields are used in the branch target calculation of the base address (word address). The RCPU branch unit copies the bit pointer into the IP field of issued compressed branch target address. The branch compressed target base address is calculated according the direct branch addressing mode.

If a branch has absolute addressing mode, the branch target base address is calculated as a sign extension of the base address portion of the LI (or BD) field.

If a branch has relative addressing mode, the branch target base address is calculated as a sum of the base address of the branch and sign extended base address portion of the branch LI (or BD) field.

Figure A-3 illustrates direct branch target address generation in “Decompression On” mode. The base address for the unconditional branch has 20 bits. This yields an unconditional branch displacement limit of 4 Mbytes. The word pointer for the conditional branch has 10 bits. This yields a conditional branch displacement limit of 4 Kbytes.

Figure A-3. Compressed Target Address Generation by Direct Branches

When a change of flow occurs, the RCPU issues the new address in compression format. The address extractor unit of the BBC extracts the base address to instruction memory. When the compressed memory word is brought to the BBC from the memory, the ICDU uses the IP field of the RCPU-issued address to decompress the instruction. The BBC provides compressed addresses of the decompressed and next instructions to the RCPU together with the decompressed instruction.

Shortened word pointer fields of direct branches in compressed mode imply some limitations on compilers that implement the PowerPC ISA architecture. They should generate binaries, with limited direct branch displacements to make the compression possible.

If a conditional branch target, generated by a compiler, must be farther than the compression mode limitation of 4 Kbytes, the compiler may generate a sequence of a conditional branch with opposite condition to skip the following unconditional branch to the original target.

If the unconditional branch range is still not big enough, the compiler can use branch chains or indirect branches.

### A.2.5 Compressed Address Generation—Indirect Branches

The indirect branch destination address is copied without any change from one of the following RCPU registers:

- LR
- CTR
- SRR0

See the *RCPU User's Manual* for more details.

These registers should contain (or be loaded by) the 32-bit compressed address of existing compressed instructions to be used for correct branching.

The LR register is automatically updated by the correct value of the “next” instruction compressed address during subroutine calls by using the ‘L’ - form of branch instructions (like *bl* or *bcl*).

The SRR0 register is updated by the correct return compressed address when exceptions are taken by the RCPU, thus the *rfi* instruction obtains the correct return address from an exception handler.

### A.2.6 Compressed Address Generation—Exceptions

Upon an exception, the RCPU core issues a regular 0xFFFF0X00 or 0x00000X00 exception vector as specified in the PowerPC ISA architecture. The compressed exception routines (or branches to them) should start (reside) at the same location in memory as noncompressed ones. The BBC ICDU passes the vectors unchanged to the MCU internal bus and provides corresponding compressed address to the RCPU together with the first exception handler instruction opcode.

This scheme allows use of the BBC exception relocation feature regardless of the MCU operational mode.

The RESET routine vector is relocated differently in decompression on and in decompression off modes. This feature may be used by a software code compression tool to guarantee that a vocabulary table initialization routine is always executed before application code is running.

## A.2.7 Class Code Compression Algorithm Rules

- Compressed instruction length may vary between 6 and 36 bits and is even.
- A compressed instruction can begin at any even location in a memory word.
- An instruction source may be compressed as a single 32-bit segment or as two independent 16-bit segments.
- Possible partitions of an instruction for compression are:
  - One 32-bit bypass segment
  - One 32-bit compressed segment
  - One 16-bit compressed segment and one 16-bit bypass segment
  - Two 16-bit compressed segments
- A bypass field is always the second field of the two possible. Length of a bypass field can be zero, 10, 15, 16 or 32 bits.
- The class prefix in a compressed instruction is 4 bits long and covers up to 16 classes.
- The vocabulary table pointer of each field may be 2 to 9 bits long.
- Vocabulary table pointers are reversed in the code. This means the pointer's LSB will be the first bit.
- In a class with a single segment of full compression, data is fetched from both memories.
- Every vocabulary table in the DECRAM is 16 bytes (8 entries) aligned (3 LSBs zeroed).

## A.2.8 Bypass Field Compression Rules

The bypass field can be either a full bypass, (i.e., the whole segment from the un-compressed instruction appears as is in the compressed instruction), or it can be represented in one of several compression encoding formats. These formats are hard-wired in the decompression module.

### A.2.8.1 Branch Right Segment Compression #1

For the MPC562/MPC564, a 15-bit bypass is used to indicate that the AA bit of a branch instruction should be inserted with a value of zero. The decompression process is performed as shown in [Figure A-4](#).

**Figure A-4. Branch Right Segment Compression #1**

This bypass is coded by a value of “13” (0xD) in the TP2LEN field of the DCCR register.

A.2.8.2 Branch Right Segment Compression #2

Also created for branch instructions on the MPC562/MPC564, a bypass of 10 bits indicates that the AA bit should be inserted with a value of zero and that the 5-bit word offset should be extended to 10 bits. The decompression process is performed as shown in [Figure A-5](#).

Figure A-5. Branch Right Segment Compression #2

This bypass is coded by a value of “12” (0xC) in the TP2LEN field of the DCCR register.

A.2.8.3 Right Segment Zero Length Compression Bypass

This MPC562/MPC564 bypass type indicates that no bypass data exists in the compressed instruction. The bypassed segment is 16 zero bits.

This bypass is coded by a value of “11” (0xB) in the TP2LEN field of the DCCR register.

A.2.9 Instruction Class Structures and Programming

The four possible compression layouts of an instruction and their attributes are listed in this section. See [Section A.4, “Decompressor Class Configuration Registers \(DCCR0-15\),”](#) for the instruction class attributes and more programming details.

A.2.9.1 Global Bypass

This MPC562/MPC564 instruction is not compressed at all.

Figure A-6. Global Bypass Instruction Layout

This class does not have a configuration register. Its prefix is hard-wired to ‘0000’ and no other attributes are needed.

### A.2.9.2 Single Segment Full Compression – CLASS\_1

This MPC562/MPC564 instruction is compressed into a single segment. The vocabulary table pointer points to an offset in tables of all RAMs (DECRAMs).

**Figure A-7. CLASS\_1 Instruction Layout**

The definition of the class includes:

- TP1 length = 2-9
- TP2 length = 0
- TP1 base address, TP2 base address = the two tables' base addresses for RAM #1 and RAM #2, respectively.
- AS, DS=0

Data brought from RAM#1 is the 16 MSBs of the decompressed instruction and data brought from RAM#2 is the 16 LSBs of the decompressed instruction.

### A.2.9.3 Twin Segment Full Compression – CLASS\_2

This MPC562/MPC564 instruction is divided into two segments. Each segment is compressed and mapped into a different vocabulary. The vocabularies reside in different RAMs. Proper programming can swap the vocabularies' locations.

**Figure A-8. CLASS\_2 Instruction Layout**

The definition of the class includes:

- TP1 length=2-9
- TP2 length=2-9
- AS=0
- For alternative #1:
  - TP1 base address = base address of segment #1 vocabulary in RAM #1
  - TP2 base address = base address of segment #2 vocabulary in RAM #2
  - DS=0
- For alternative #2:
  - TP1 base address = base address of segment #2 vocabulary in RAM #1
  - TP2 base address = base address of segment #1 vocabulary in RAM #2
  - DS=1

Alternatives #1 and #2 are referred to as CLASS\_2a and CLASS\_2b respectively.

#### A.2.9.4 Left Segment Compression and Right Segment Bypass – CLASS\_3

For the MPC562/MPC564, the instruction is divided into two segments. The left segment is compressed and mapped into a vocabulary. The vocabulary location is programmable. The right segment is either fully bypassed by a 16-bit field or by a shorter field which is decompressed according to fixed rules.

**Figure A-9. CLASS\_3 Instruction Layout**

The definition of the class includes

- TP1 length=2-9
- TP2 length=0xB, 0xC, 0xD, or 0xE indicating a 0, 10, 15 or 16 bit bypass, respectively.
- TP1 base address = base address of segment #1 vocabulary in RAM #1, if it exists there.
- TP2 base address = base address of segment #1 vocabulary in RAM #2, if it exists there.
- DS=0
- AS=0 or 1 directing access to the vocabulary in RAM #1 or RAM #2, respectively.

When the vocabulary is located in RAM #1, the class will be referred to as CLASS\_3a and when the vocabulary is located in RAM #2, the class will be referred to as CLASS\_3b.

### A.2.9.5 Left Segment Bypass and Right Segment Compression—CLASS\_4

This MPC562/MPC564 instruction is divided into two segments. The left segment is either fully bypassed by a 16-bit field or by a shorter field which is decompressed according to fixed rules. The right segment is compressed and mapped into a vocabulary. The vocabulary location is programmable. The compressed fields must be swapped in the compressed instruction order to follow the rule that bypass appears only in the second field of a compressed instruction.

**Figure A-10. CLASS\_4 Instruction Layout**

The definition of the class includes:

- TP1 length=2-9
- TP2 length=0xB, 0xC, 0xD, or 0xE indicating a 0, 10, 15 or 16 bit bypass, respectively.
- TP1 base address = base address of segment #1 vocabulary in RAM #1, if it exists there
- TP2 base address = base address of segment #1 vocabulary in RAM #2, if it exists there
- DS=1
- AS=0 or 1 directing access to the vocabulary in RAM #1 or RAM #2, respectively.

When the vocabulary is located in RAM #1, the class is referred to as CLASS\_4band when the vocabulary is located in RAM #2, the class is referred to as CLASS\_4a. Refer to [Table A-4](#).

### A.2.10 Instruction Layout Programming Summary

[Table A-4](#) summarizes the programming for all possible compressed instruction layouts.

The un-compressed instruction of two half-words are referred as H1 & H2. The compressed instruction can be built out of: (1) X1 field – representing a vocabulary pointer for encoding of either H1 or H1+H2; (2) X2 field – representing a vocabulary pointer for encoding of H2; and (3) BP – representing a bypass field.

Vocabularies V1 and V2 refer to the 16 MSB and 16 LSB of the uncompressed instruction, respectively.

### A.2.11 Compression Process

The compression process is implemented by the following steps. See [Figure A-11](#).

- User code compilation/linking
- Vocabulary and class generation
- User application code compression by a software compression tool

The vocabulary and class configurations are generated by profiling the static code, based on the instruction class algorithm.

The code compression can be created by using either default or specific application vocabularies, generated at the previous step. In case of default vocabularies, the generation step can be omitted, but compression efficiency is reduced.

The compression tool replaces regular PowerPC ISA instructions with a compressed representation that contains fewer bits. The tool also updates offset fields in direct branch instructions to include a compressed format offset (four bits of IP and word offset). Thus, maximum branch offsets in decompression on mode are reduced. The RCPU uses the word offset for direct branch target address computation. The RCPU provides the instruction pointer portion of the branch offset field to the decompression unit as it is represented in the branch instruction.

Figure A-11. Code Compression Process

## A.2.12 Decompression

- The instruction code is stored in the memory in the compressed format
- The vocabularies are stored in a dedicated ICDU RAM (DECRAM)
- The class configuration is stored in a dedicated ICDU register (DCCR)
- The decompression is done on-line by the dedicated decompressor unit
- Decompression flow is as follows: (See [Figure A-12](#))
  - RCPU provides to the BBC a 2-bit aligned change of flow (COF) address

- The ICDU:
  - Converts the COF address to a word-aligned physical address to access the memory
  - Fetches the compressed instruction code from the memory, decompresses it and delivers non-compressed instruction code, together with the bit-aligned next instruction address, to the RCPU.

Figure A-12. Code Decompression Process

### A.2.13 Compression Environment Initialization

In order to commence the execution of the compressed code, the DECRAM and the class information (in the DCCR registers) must be programmed. The data to be programmed is supplied by the compressor tool and the vocabulary generator. There are two initialization scenarios:

1. Wake up in decompression off mode — If the chip wakes up with decompression disabled, the initialization routine can be executed at any time before entering decompression on mode. After the compression environment is initialized, the operational mode would be changed to decompression on.
2. Wake up in decompression on mode — If the chip wakes up in decompression on mode, it has to process compressed instructions without the vocabularies and class parameters. Thus, all instructions executed until the end of the initialization routine should be compressed in the global bypass format. DECRAM loading is an essential part of this initialization routine. After DECRAM loading, efficient compressed code may be used.

## A.2.14 Compression/Non-Compression Mode Switch

The MPC562/MPC564 allows the option to switch between compressed and non-compressed code on the fly. There are two ways to switch between the modes, as shown in [Section A.2.14.1, “Compression Definition for Exception Handlers,”](#) and [Section A.2.14.2, “Running Mixed Code.”](#)

### A.2.14.1 Compression Definition for Exception Handlers

The MPC562/MPC564 can wake up upon reset with all the exception handlers defined to be compressed (or not), so when any exception occurs or completes, the hardware switches to the appropriate mode without software intervention.

### A.2.14.2 Running Mixed Code

If the compression mode is enabled on the MPC562/MPC564, the software can switch between compressed and non-compressed code by setting (or clearing) the compression mode bit in the RCPU MSR register. This is done by setting/clearing bit 29 in the RCPU SRR1 register (SRR1 gets loaded into the MSR register when the rfi instruction is executed. Bit 29 is the DCMPEM bit of the MSR). The next step is to load SRR0 with a target address in compressed/non-compressed format and then executing an rfi instruction. Following is a suggested routine to execute the switch in both directions (must be run in supervisor mode when RCPU MSR[PR] bit is cleared):

```
# R30 contains destination address in appropriate format
.set turn_on_compression_bit_mask, 4
.set turn_off_compression_bit_mask, 0xffffb
mfmsr    r31
# to go to compressed code
ori      r31,r31,turn_on_compression_bit_mask
# or alternative to go to uncompressed code:
andi     r31,r31,turn_off_compression_bit_mask
mtspr    NRI,r0 # Disable external interrupts
mtspr    SRR1,r31
mtspr    SRR0,r30 # destination address load
rfi      # branch and modify MSR
```

#### NOTE

When BBCMCR[EN\_COMP] (bit 21) is set, modification of MSR[DCMPEN] (bit 29) by mtmsr instruction is strictly forbidden. It may cause the machine to hang until reset.

## A.3 Operation Modes

### A.3.1 Instruction Fetch

The MPC562/MPC564 provides two instruction fetch modes: decompression off and decompression on.

The operational modes are defined by RCPU MSR[DCMPEN] bit. If the bit is set, the mode is decompression on. Otherwise, it is in decompression off.

### A.3.1.1 Decompression Off Mode

Refer to [Section 4.2.1.1, “Decompression Off Mode”](#) for an explanation of decompression off.

### A.3.1.2 Decompression On Mode

In this mode, the MPC562/MPC564’s RCPU sends the two-bit aligned change of flow (COF) address to the BBC. The BIU transfers the word portion of the address to the U-bus. The BBC continues to pre-fetch the data from the consequent memory addresses regardless of whether the RCPU requests them in order to supply data to the ICDU.

In the MPC562/MPC564, the data coming from the instruction memory is not provided directly to the RCPU, but loaded into the ICDU for decompression. Decompressed instruction code together with “next instruction address” are provided to the RCPU whenever it requires another instruction fetch.

All addresses issued by the BIU to the U-bus are transferred in parallel to the IMPU. The IMPU compares the address of the access to its region programming. If any protection violation is detected by the IMPU, the current U-bus access is aborted by the BIU and an instruction storage protection error exception is signaled to the RCPU.

Show cycle and program trace access attributes accompanying the COF RCPU access only are forwarded by the BIU along with the U-bus access. Additional information about the IP of the compressed instruction address is provided on the U-bus data bus. Refer below to [Section A.3.1.2.1, “Show Cycles in Decompression On Mode,”](#) for more details.

In this mode the MPC562/MPC564’s ICDU DECRAM is used as a decompressor vocabulary storage and may not be used as a general purpose RAM.

#### A.3.1.2.1 Show Cycles in Decompression On Mode

In the MPC562/MPC564’s decompression on mode, the instruction address consists of an instruction base address and four bits of the instruction bit pointer. In order to provide the capability to show full instruction address, including instruction bit pointer on the external bus, show cycle information is presented not only on the address bus, but also on some bits of the data bus:

- ADDR[0:29] – show the value of the base address of compressed instruction (word pointer into the memory)
- DATA[0] – shows in which mode the MPC562/MPC564 is operating
  - 0 = decompression off mode
  - 1 = decompression on mode
- DATA[1:4] – represent an instruction bit pointer within the word.

Instruction show cycle bus transactions have the following characteristics (see [Figure 9-41](#)):

- One clock cycle
- Address phase only; in decompression on mode part of the compressed address is driven on data lines together with address lines. The external bus interface adds one clock delay between a read cycle and such show cycle.
- $\overline{\text{STS}}$  assertion only (no  $\overline{\text{TA}}$  assertion)

## NOTE

The BBCMCR[DECOMP\_SC\_EN] bit determines if the data portion (DATA[0:4]) of the instruction show cycle is driven or not, regardless of decompression mode (BBCMCR[EN\_COMP] bit)

### A.3.2 Vocabulary Table Storage Operation

The MPC562/MPC564 uses DECRAM for decompressor vocabulary tables (VT1 and VT2) storage in decompression on mode. The ICDU utilizes DECRAM as two separately accessed 1-Kbyte RAM arrays (16 bits wide) that are accessed via internal ICDU buses. The VTs should be loaded before the decompression process starts. In order to allow decompression, the DECRAM must be disabled for the U-bus accesses after VTs and decompressor class configuration registers (DCCRs) are initialized.

### A.3.3 READI Compression

Setting BBCMCR[DECOMP\_SC\_EN] when decompression is enabled allows READI to track the compressed code (see [Chapter 24, “READI Module”](#)). BBCMCR[DECOMP\_SC\_EN] should not be set if there is no intention to use compressed code, as it will degrade U-bus performance. The show cycle may be delayed by one clock by the USIU if the show cycle occurs after an external device read cycle. Refer to [Section 24.6.5.2, “Compressed Code Mode Guidelines.”](#)

The ICTRL register must be programmed such that a show cycle will be performed for all changes in the program flow (ISCTL field = 0b01), or the PTM bit must be set and ISCTL must be set to a value other than 0b11. (See [Table A-2.](#))

#### A.3.3.1 I-Bus Support Control Register (ICTRL)

| 1                       | 11                        | RCPU is not serialized (normal mode) and no show cycles will be performed for fetched instructions                  |

## A.4 Decompressor Class Configuration Registers (DCCR0-15)

The DCCR fields are programmed to achieve maximum flexibility in the vocabulary tables placement into the two DECRAM banks under constraints, implied by hardware, which are:

- A bypass field must always be in the second field of the compressed instruction

- When fetching 32 bits of decompressed instruction from the DECRAM, each 16 bits will be read from different RAM banks.

The DCCR registers should be programmed with data supplied by the code compression tool, in order to be correlated with the compressed code.

**Figure A-14. Decompressor Class Configuration Registers<sup>1</sup> (DCCR<sub>x</sub>)**

- The DCCR0 register is hard coded for the “bypass decompressor class.” Write accesses do not affect the DCCR0 register. The DCCR0 register will always return 0x0000 0000 when read.

**Table A-3. DCCR0-DCCR15 Field Descriptions**

| Bits  | Name   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

| Left Segment Bypassed, Right Segment Compression, Vocabulary In RAM #2                          | CLASS 4a           | 2                   |                     | —               | —      | 2               | V2     | 1  |    | X2 BP <sup>2</sup>            |

<sup>1</sup> X1, X2 - pointers to vocabularies

<sup>2</sup> BP - the bypassed data

## Appendix B

### Internal Memory Map

This appendix includes the following memory maps:

- Table B-1. SPR (Special Purpose Registers)
- Table B-2. UC3F Flash Array
- Table B-3. DECRAM SRAM Array
- Table B-4. BBC (Burst Buffer Controller Module)
- Table B-5. USIU (Unified System Interface Unit)
- Table B-6. CDR3 Flash Control Registers EEPROM (UC3F)
- Table B-7. DPTRAM Control Registers
- Table B-8. DPTRAM Memory Arrays
- Table B-9. Time Processor Unit 3 A and B (TPU3 A and B)
- Table B-10. QADC64E A and B (Queued Analog-to-Digital Converter)
- Table B-11. QSMCM (Queued Serial Multi-Channel Module)
- Table B-12. Peripheral Pin Multiplexing (PPM) Module
- Table B-13. MIOS14 (Modular Input/Output Subsystem)
- Table B-14. TouCAN A, B and C (CAN 2.0B Controller)
- Table B-15. UIMB (U-Bus to IMB Bus Interface)
- Table B-16. CALRAM Control Registers
- Table B-17. CALRAM Array
- Table B-18. READI Module Registers

Memory map tables use the notation shown below:

**Notations Used in the Access Column**

S = Supervisor access only

U = User access

T = Test access

**Notations Used in the Reset Column**

— (em dash) = Untouched

S =  $\overline{\text{SRESET}}$

H =  $\overline{\text{HRESET}}$

M =  $\overline{\text{Module Reset}}$

POR =  $\overline{\text{Power-On Reset}}$

U = Unchanged

X = Unknown

R =  $\overline{\text{RSTI}}$

In each table, the codes in the Reset column indicate which reset affects register values.

**Table B-1. SPR (Special Purpose Registers)**

| Address | Access | Symbol | Register                                                                                           | Size | Reset |
|---------|--------|--------|----------------------------------------------------------------------------------------------------|------|-------|
| CR      | U      | CR     | Condition State Register<br>See <a href="#">Section 3.7.4</a> for bit descriptions.                | 32   | —     |

<sup>1</sup> Entire register is locked if bit 15 (DLK) is set.

<sup>2</sup> Write once after power on reset (POR).

<sup>3</sup> Must use the key register to unlock if it has been locked by a key register, see [Section 8.8.3.2, “Keep-Alive Power Registers Lock Mechanism.”](#)

<sup>4</sup> Locked after Power on Reset (POR). A write of 0x55CCAA33 must be performed to the key register to unlock. See [Section 8.8.3.2, “Keep-Alive Power Registers Lock Mechanism.”](#)

<sup>5</sup> Can have bits 0:11 (MF bits) write-protected by setting bit 4 (MFPDL) in the SCCR register to 1. Bit 21 (CSRC) and bits 22:23 (LPM) can be locked by setting bit 5 (LPML) of the SCCR register to 1.

<sup>6</sup> Bit 24 (CSR) is write-once after soft reset.

<sup>1</sup> Bit 10 (TPU3) and bit 11 (T2CSL) are write-once. Bits 1:2 (TCR1P) and bits 3:4 (TCR2P) are write-once if PWOD is not set in the TPUMCR3 register. This register cannot be accessed with a 32-bit read. It can only be accessed with an 8- or 16-bit read.

<sup>2</sup> Some TPU registers can only be read or written with 16- or 32-bit accesses. 8-bit accesses are not allowed.

<sup>3</sup> S/U = Supervisor accessible only if SUPV = 1 or unrestricted if SUPV = 0. Unrestricted registers allow both user and supervisor access. The SUPV bit is in the TPUMCR register.

<sup>4</sup> TPU code development (Debug) register

<sup>5</sup> Bits 9:10 (ETBANK), 14 (T2CF), and 15 (DTPU) are write-once.

## Appendix C

### Clock and Board Guidelines

The MPC561/MPC563 built-in PLL, oscillator, and other analog and sensitive circuits require that the board design follow special layout guidelines to ensure proper operation of the chip clocks. This appendix describes how the clock supplies and external components should be connected in a system. These guidelines must be fulfilled to reduce switching noise which is generated on internal and external buses during operation. Any noise injected into the sensitive clock and PLL logic reduces clock performance. The USIU maintains a PLL loss-of-lock warning indication that can be used to determine the clock stability in the MPC561/MPC563.

## C.1 MPC56x Device Power Distribution

1. The main power supply may optionally supply operating current to reduce the keep-alive current requirements. See the circuit in [Section 8.11.1, "System Clock Control Register \(SCCR\)."](#)
2. Resistor R<sub>1</sub> is currently not required. Space should be left on the board to add it in the future if necessary.
3. All 100 nF capacitors should be placed close to the pin.
4. C<sub>L</sub> is a function of specific crystal C<sub>L</sub> = C<sub>X</sub> + C<sub>Y</sub>. See [Section C.2, "Crystal Oscillator External Components."](#)
5. This flash power supply is available on MPC563/564. VDDF should be connected to VDD as close as possible to the chip, preferably directly to an inner power plane of the board.
6. See C.3.3 for more information.
7. "All component values shown are nominal. Component tolerance should be considered when designing the system."

**Figure C-1. MPC561/MPC563 Power Distribution Diagram — 2.6 V**

1. 10 ohms is recommended because  $I_{REF}(\max)$  is 250  $\mu A$  per QADC64. 10 Ohm x 2 modules x 250  $\mu A$  = 5 mV (approximately one count, or one LSB)
2. The QADC64 circuit design allows for VDDA being less than VRH with a value of up to 10 ohms in this RC filter.
3. This size of resistor  $R_2$  depends on the sensor load current. It should be sized to match the voltage at VRH.

**Figure C-2. Power Distribution Diagram — 5 V and Analog**

# C.2 Crystal Oscillator External Components

1. Resistor  $R_1$  is currently not required. Space should be left on the board to add it in the future if necessary.

**Figure C-3. Crystal Oscillator Circuit**

**Table C-1. External Components Value For Different Crystals (Q1)**

| Component | NDK CP32C<br>20 MHz | KINSEKI CX-11F<br>20 MHz | MURATA CCSTC<br>4 MHz | Units |
|-----------|---------------------|--------------------------|-----------------------|-------|
| $C_L^1$   | 6                   | 14                       | —                     | pF    |
| $R_1^3$   | 1MEG <sup>3</sup>   | 1MEG <sup>3</sup>        | 1MEG <sup>3</sup>     | Ohm   |
| $C_X$     | 6                   | 16                       | — <sup>2</sup>        | pF    |
| $C_Y$     | 6                   | 16                       | —                     | pF    |

<sup>1</sup>  $C_L$  according to crystal specification,  $C_L = C_X + C_Y$ .

<sup>2</sup> The Murata ceramic resonator includes the load capacitors. (8pF should be selected)

<sup>3</sup> Resistor  $R_1$  is currently not required. Space should be left on the board to add it in the future if necessary.

The load capacitances specified in [Table C-1](#) include all stray capacitance.

Tolerance of the capacitors is  $\pm 10\%$ .

The oscillator capacitors  $C_X$  and  $C_Y$  were calculated as follows:

$$C_A = C_B = 2C_L$$

$$C_A = C_X + C_{PAD} + C_{SOCKET}$$

$$C_B = C_Y + C_{PAD} + C_{SOCKET}$$

Where:

$C_L$  is load capacitance

$C_{PAD}$  is pad capacitance

- XTAL pad capacitance is  $C_{PAD} = \sim 7$  pF

- EXTAL pad capacitance is  $C_{PAD} = \sim 7 \text{ pF}$

$C_{SOCKET}$  is socket and board trace capacitance

- Socket capacitance  $C \leq 1 \text{ pF}$
- Board trace capacitance  $C \leq 1 \text{ pF}$ . This should be low since the crystal must be located very close to the chip.

## C.2.1 KAPWR Filtering

The KAPWR signal is the MPC561/MPC563 keep-alive power. KAPWR is used for the crystal oscillator circuit, and should be isolated from the noisy supplies. It is recommended that an RC filter be used on KAPWR, or bypass capacitors that are located as close as possible to the part.

Note: A filter cut off frequency of 500Hz is recommended, however this will result in a capacitor size of 33uF using a 10 Ohm resistor. This may be too expensive or large for the system. In this case the filter shown with cut-off frequency of 160kHz will suffice.

Figure C-4. RC Filter Example

Figure C-5. Bypass Capacitors Example (Alternative)

## C.2.2 PLL External Components

VDDSYN and VSSSYN are the PLL dedicated power supplies. These supplies must be used only for the PLL and isolated from all other noisy signals in the board. VDDSYN could be isolated with RC filter (see [Figure C-6](#)), or LC filter. The maximum noise allowed on VDDSYN, and VSSSYN is 50 mV with typical cut-off frequency of 500 Hz.

Note: A filter cut off frequency of 500Hz is recommended, however this will result in a capacitor size of 33uF using a 10 Ohm resistor. This may be too expensive or large for the system. In this case the filter shown with cut- off frequency of 160kHz will suffice.

**Figure C-6. RC Filter Example**

Note: A filter cut off frequency of 500Hz is recommended, however this will result in a capacitor size of 15uF using a 8.2mH inductor. This may be too expensive or large for the system. In this case the filter shown with cut- off frequency of 5.5kHz will suffice.

**Figure C-7. LC Filter Example (Alternative)**

### C.2.3 PLL Off-Chip Capacitor $C_{XFC}$

$C_{XFC}$  is the PLL feedback capacitor. It must be located as close as possible to the XFC and VDDSYN pads. The maximum noise allowed on XFC is 50 mV peak-to-peak with a typical cut-off frequency of 500 Hz.

The XFC capacitor creates a low pass filter in the PLL loop. The filter output feeds the PLL VCO. The capacitor is charged and discharged by short current pulses, generated by the phase detector. So the capacitor leakage and absorption directly affect the AC component in the VCO input voltage that creates PLL output clock jitter. Therefore, the dielectric quality of  $C_{XFC}$  should be high.

Smaller  $C_{XFC}$  makes the PLL faster to gain lock but less stable. Higher  $C_{XFC}$  makes the PLL more stable but slower to gain lock. Because each board layout and application is unique,  $C_{XFC}$  must be evaluated in a system.

The minimum required value (including capacitor tolerance) for  $C_{XFC}$  is determined by the following two cases:

$$0 < (MF+1) < 4$$

$$C_{XFC} = (1130 * (MF+1) - 80) \text{ pF}$$

$$(MF+1) \geq 4$$

$$C_{XFC} = (2100 * (MF+1)) \text{ pF}$$

MF is the multiplication factor in the PLPRCR register (refer to [Section 8.11.2, “PLL, Low-Power, and Reset-Control Register \(PLPRCR\)”](#) for more information).

Figure C-8. PLL Off-Chip Capacitor Example

## C.3 PLL and Clock Oscillator External Components Layout Requirements

### C.3.1 Traces and Placement

Traces connecting capacitors, crystal, resistor should be as short as possible. Therefore, the components (crystal, resistor and capacitors) should be placed as close to the oscillator pins of the MPC561/MPC563 as possible.

The voltage to the VDDSYN pin should be well regulated and the pin should be provided with an extremely low impedance path from the VDDSYN filter to the VDDSYN pad.

The VSSSYN pin should be provided with an extremely low impedance path in the board. All the filters for the supplies should be located as close as possible to the chip package. It is recommended to design individual VSSSYN plane to improve VSSSYN quietness.

### C.3.2 Grounding/Guarding

The traces from the oscillator pins and PLL pins of the MPC561/MPC563 should be guarded from all other traces to reduce crosstalk. It can be provided by keeping other traces away from the oscillator circuit and placing a ground plane around the components and traces.

### C.3.3 IRAMSTBY Regulator Circuit

IRAMSTBY is the data retention power supply for all on-board RAM arrays (CALRAM, DPTRAM, DECRAM). It has a shunt regulator circuit to divert excess current to ground in order to regulate voltage on the IRAMSTBY power supply pin. IRAMSTBY should be connected to a positive power supply, via a resistor, and bypassed by a capacitor to ground as shown in [Figure C-9](#).

**Figure C-9. IRAMSTBY Regulator Circuit**

The IRAMSTBY regulator has a minimum operating current required for the circuit to regulate. This minimum current, along with the range of regulation voltages, determines the regulator's limits of operation. Also, the regulator has a maximum current that it can sink without the regulated voltage rising out of range.

**Table C-2. IRAMSTBY Regulator Operating Specifications**

| Parameter         | Minimum    | Typical | Maximum |
|-------------------|------------|---------|---------|
| Supply Current    | 50 $\mu$ A | N/A     | 1.75 mA |
| Regulated Voltage | 1.35 V     | 1.70 V  | 1.95 V  |

1. Operating Conditions: -40 C to 150 C, all process variations.
2. Supply Current includes SRAM array standby currents.

The boundary equations which describe the limits of the operating parameters for the IRAMSTBY regulator are as follows:

$$\frac{(V_{\text{SUPPLYMIN}} - 1.95 \text{ V})}{R_{\text{SUPPLY}}} > 50 \mu\text{A}$$

$$\frac{(V_{\text{SUPPLYMAX}} - 1.35 \text{ V})}{R_{\text{SUPPLY}}} < 1.75 \text{ mA}$$

# Appendix D

## TPU3 ROM Functions

The following pages provide brief descriptions of the pre-programmed functions in the TPU3. For detailed descriptions, refer to the programming note for the individual function. The Freescale *TPU Literature Pack* provides a list of available programming notes.

### D.1 Overview

The TPU3 contains 4 Kbytes of microcode ROM. It can have up to 8 Kbytes of memory and a maximum of four entry tables (see [Figure D-1](#)). This appendix defines the standard ROM functions for the MPC561/MPC563.

<sup>1</sup> The DPTRAM is located at 0x30 2000.

**Figure D-1. TPU3 Memory Map**

The TPU3 can address up to 8 Kbytes of memory at any one time. It has 4 Kbytes of internal ROM, located in banks 0 and 1, and 8 Kbytes of dual-ported SRAM (DPTRAM), located in banks 0, 1, 2, and 3. As only one type of memory can be used at a time, the TPU3 must either use the internal ROM or the SRAM. Functions from both memory types cannot be used in conjunction.

A new feature of the TPU3 microcode ROM is the two 16-function entry tables in the 4 Kbytes of internal ROM. The ETBANK field in the TPUMCR2 register, written once after reset, determines which one of

these entry tables the RCPU selects. Though the TPU3 can access either entry table, only one table can be used at a time and functions from the tables cannot be mixed. The default entry table, located in bank 0, is identical to the standard microcode ROM in the TPU2, making any RCPU code written for the TPU2 interchangeable with the TPU3. The functions in the default entry table in bank 0 are listed in [Table D-1](#).

**Table D-1. Bank 0 and Bank 1 Functions**

| Function Number | Bank 0 Functions (Default)                         | Bank 1 Functions                                   |
|-----------------|----------------------------------------------------|----------------------------------------------------|
| 0xF             | PTA (Programmable Time Accumulator)                | PTA (Programmable Time Accumulator)                |
| 0xE             | QOM (Queued Output Match)                          | QOM (Queued Output Match)                          |
| 0xD             | TSM (Table Stepper Motor)                          | TSM (Table Stepper Motor)                          |
| 0xC             | FQM (Frequency Measurement)                        | FQM (Frequency Measurement)                        |
| 0xB             | UART (Universal Asynchronous Receiver/Transmitter) | UART (Universal Asynchronous Receiver/Transmitter) |
| 0xA             | NITC (New Input Capture/Input Transition Counter)  | NITC (New Input Capture/Input Transition Counter)  |
| 9               | COMM (Multiphase Motor Commutation)                | COMM (Multiphase Motor Commutation)                |
| 8               | HALLD (Hall Effect Decode)                         | HALLD (Hall Effect Decode)                         |
| 7               | MCPWM (Multi-Channel Pulse Width Modulation)       | MULTI (Multi TPU) <sup>1</sup>                     |
| 6               | FQD (Fast Quadrature Decode)                       | FQD (Fast Quadrature Decode)                       |
| 5               | PPWA (Period/Pulse Width Accumulator)              | ID (Identification)                                |
| 4               | OC (Output Compare)                                | OC (Output Compare)                                |
| 3               | PWM (Pulse Width Modulation)                       | PWM (Pulse Width Modulation)                       |
| 2               | DIO (Discrete Input/Output)                        | DIO (Discrete Input/Output)                        |
| 1               | SPWM (Synchronized Pulse Width Modulation)         | RWTPIN (Read/Write Timers and Pin)                 |
| 0               | SIOP (Serial Input/Output Port)                    | SIOP (Serial Input/Output Port)                    |

<sup>1</sup> The MULTI functions are only on revision D and later of the MPC561 and not available on revision B and earlier of the MPC563.

The functions in the bank 1 entry table are identical to those in bank 0, except in three cases. Function 1, SPWM in the bank 0 table, has been replaced by RWTPIN, a function that allows a read and write to the TPU3 timebases and corresponding pin. Function 5, PPWA in the bank 0 table, is an identification (ID) function in the bank 1 table that provides the microcode ROM revision number. Function 7, MCPWM, has been replaced by MULTI in later silicon revisions. The functions in the bank 1 entry table are listed in [Table D-1](#).

The RCPU selects which entry table to use by setting the ETBANK field in the TPUMCR2 register. This register is written once after reset. Although one entry table is specified at start-up, in some cases it is possible to use functions from both tables without resetting the microcontroller. A customer may, for example, wish to use the ID function from bank 1 to verify the TPU3 microcode version but then use the MCPWM function from bank 0. As a customer will typically only run the ID function during system

configuration, and not again after that, the bank 1 entry table can be changed to the bank 0 entry table using the soft reset feature of the TPU3. This procedure is described in the following steps:

1. Set ETBANK field in TPUMCR2 to 0b01 to select the entry table in bank 1
2. Run the ID function
3. Stop the TPU3 by setting the STOP bit in the TPUMCR to one
4. Reset the TPU3 by setting the SOFTRST bit in the TPUMCR2 register
5. Wait at least nine clocks
6. Clear the SOFTRST bit in the TPUMCR2 register

The TPU3 stays in reset until the RCPU clears the SOFTRST bit. After the SOFTRST bit has been cleared, the TPU3 will be reset and the entry table in bank 0 will be selected by default. To select the bank 0 entry table, write 0b00 to the ETBANK field in TPUMCR2. Always initialize any write-once register to ensure that an incorrect value is not accidentally written.

The sections below document the bank 0 and bank 1 functions listed in [Table D-1](#) of the TPU3 ROM module.

## D.2 Programmable Time Accumulator (PTA)

PTA starts on a rising or falling edge and accumulates, over a programmable number of periods or pulses, a 32-bit sum of the total high time, low time, or input signal period. After the specified number of periods or pulses, the PTA generates an interrupt request.

One to 255 period measurements can be accumulated before the TPU3 interrupts the RCPU, providing instantaneous or average frequency measurement capability. See Freescale TPU Programming Note *Programmable Time Accumulator TPU Function (PTA)*, (TPUPN06/D). [Figure D-2](#) shows all of the host interface areas for the PTA function.

### CONTROL BITS

|                                                                                                                               | NAME                     | OPTIONS                                                                                                                    | ADDRESSES           |

Figure D-2. PTA Parameters

### D.3 Queued Output Match TPU3 Function (QOM)

QOM can generate single- or multiple-output match events from a table of offsets in parameter RAM. Loop modes allow complex pulse trains to be generated once, a specified number of times, or continuously. QOM can be used with other TPU3 channels in a variety of ways: the function can be triggered by a link from the channel, the reference time for the sequence of matches can be obtained from it, or the channel can be used as a discrete output pin. QOM can generate pulse-width modulated waveforms, including waveforms with high times of 0 or 100%. See Freescale TPU3 Programming Note *Queued Output Match TPU Function (QOM)*, (TPUPN01/D).

[Figure D-3](#) shows all of the host interface areas for the QOM function. The bit encodings shown in [Table D-2](#) describe the corresponding fields in parameter RAM.

Table D-2. QOM Bit Encoding

| A | Timebase Selection   |
|---|----------------------|
| 0 | Use TCR1 as Timebase |
| 1 | Use TCR2 as Timebase |

|   | Edge Selection        |
|---|-----------------------|
| 0 | Falling Edge at Match |
| 1 | Rising Edge at Match  |

| B:C | Reference for First Match    |
|-----|------------------------------|
| 00  | Immediate TCR Value          |
| 01  | Last Event Time              |
| 10  | Value Pointed to by REF_ADDR |
| 11  | Last Event Time              |

Figure D-3. QOM Parameters

## D.4 Table Stepper Motor (TSM)

The TSM function provides acceleration and deceleration control of a stepper motor with up to 58 programmable step rates. TSM uses a table in parameter RAM, rather than an algorithm, to define the stepper motor acceleration profile, allowing full definition of the profile. In addition, a slew rate parameter allows fine control of the motor's terminal running speed independent of the acceleration table. The RCPU writes a desired position, and the TPU3 accelerates, slews, and decelerates the motor to the required position. Full- and half-step support is provided for two-phase motors. See Freescale TPU3 Programming Note *Table Stepper Motor TPU Function (TSM)*, (TPUPN04/D).

[Figure D-4](#) and [Figure D-5](#) show all of the host interface areas for the TSM function when operating in master or slave mode.

**Figure D-5. TSM Parameters — Slave Mode**

## D.5 Frequency Measurement (FQM)

FQM counts the number of TPU-channel input pulses during a user-defined window period. The function has single-shot and continuous modes. In continuous mode, no pulses are lost between sample windows, and the user can select whether to detect pulses on the rising or falling edge. This function is intended for high-speed measurement. (Measurement of slow pulses with noise rejection can be made with PTA.) See Freescale TPU Programming Note *Frequent Measurement TPU Function (FQM)*, (TPUPN03/D).

Figure D-6 shows all of the host interface areas for the FQM function.

**Figure D-6. FQM Parameters**

## D.6 Universal Asynchronous Receiver/Transmitter (UART)

The UART uses one or two TPU3 channels to provide asynchronous communications. Data word length is programmable from 1 to 14 bits. The function supports detection or generation of even, odd, and no parity. Baud rate is freely programmable and can be higher than 100 Kbaud. Eight bidirectional UART channels running in excess of 9600 baud can be implemented on the TPU3. See Freescale TPU3 Programming Note *Asynchronous Serial Interface TPU Function (UART)*, (TPUPN07/D).

[Figure D-7](#) and [Figure D-8](#) show all of the host interface areas for the UART function in transmitting and receiving modes.

## CONTROL BITS

Figure D-8. UART Receiver Parameters

## D.7 New Input Capture/Transition Counter (NITC)

NITC allows, for a specified number of transitions, a TPU3 channel to: capture the value of a TCR (test configuration register) or any specified location in parameter RAM and then generate an interrupt request to notify the bus master (times of the two most recent transitions remain in parameter RAM), capture input continually or detect a specific number of transitions and end channel activity until reinitialization, or generate a link to other channels after the transitions have taken place. See Freescale TPU Programming Note *New Input Capture/Input Transition Counter TPU Function (NITC)*, (TPUPN08/D).

[Figure D-9](#) shows all of the host interface areas for the NITC function.

## D.8 Multiphase Motor Commutation (COMM)

The COMM function generates phase commutation signals for a variety of brushless motors, including three-phase brushless direct current motors. It derives the commutation state directly from the position decoded in FQD, eliminating the need for hall effect sensors.

The state sequence is implemented as a user-configurable state machine, providing a flexible approach with other general applications. A RCPU offset parameter is provided to allow the RCPU to advance or retard all switching angles on the fly. This feature is useful for torque maintenance at high speeds. See Freescale TPU Programming Note *Multiphase Motor Commutation TPU Function (COMM)*, (TPUPN09/D).

[Figure D-10](#) and [Figure D-10](#) show all of the host interface areas for the COMM function.

## D.9 Hall Effect Decode (HALLD)

The HALLD function decodes the sensor signals from a brushless motor (the function supports two- or three-sensor decoding) and a direction input from the RCPU into a state number. The decoded state number is written into a COMM channel, which outputs the required commutation drive signals. In addition to brushless motor applications, the function can have more general applications, such as decoding “option” switches. See Freescale TPU Programming Note *Hall Effect Decode TPU Function (HALLD)*, (TPUPN10/D).

[Figure D-11](#) shows all of the host interface areas for the HALLD function.

Figure D-11. HALLD Parameters

## D.10 Multichannel Pulse-Width Modulation (MCPWM)

MCPWM generates pulse-width modulated outputs with full 0 to 100% duty cycle range independent of other TPU3 activity. This capability requires two TPU3 channels plus an external gate for one PWM. (A simple one-channel PWM capability is supported by the QOM function.)

Multiple PWMs generated by MCPWM have two types of high time alignment: edge aligned and center aligned. Edge-aligned mode uses  $n + 1$  TPU3 channels for  $n$  PWMs, and center-aligned mode uses  $2n + 1$  channels. Center-aligned mode allows a user to define “dead time” so that two PWMs can be used to drive an H-bridge without destructive current spikes. This feature is important for motor control applications. See Freescale TPU Programming Note *Multichannel PWM TPU Function (MCPWM)*, (TPUPN05/D).

[Figure D-12](#) through [Table D-17](#) shows the host interface areas for the MCPWM function in each mode.

**Figure D-17. MCPWM Parameters — Slave Ch B Inverted Center-Aligned Mode**

## D.11 Multi TPU (MULTI)

The MULTI function consists of four sub-functions:

- |         |                                                                                                                                                                                                                                                                                                                                                                                                                |
|---------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| FRINC:  | A free running incrementing 32-bit counter. The counter frequency is determined by a variable parameter 'TICKS' and either TCR1 or TCR2 can be used as a timebase. This function runs continuously without service from the RCPU and can only be stopped by setting its priority to zero.                                                                                                                      |
| FRDEC:  | A free running 32-bit decrementing counter, similar to FRINC but with the additional feature that it can be programmed to generate an interrupt when the counter reaches zero.                                                                                                                                                                                                                                 |
| PWM_IN: | This function analyses a PWM-input signal by measuring a selectable number of periods. It adds both periods as well as high-time for the selected number of periods.                                                                                                                                                                                                                                           |
| SPEED:  | This function measures periods from a defined edge to the next defined edge. The measurement is not specified for a number of periods, but is continuous. If the result is read regularly, the function measures the time for the number of periods detected between the two reads. In other words, the function averages the periods between two consecutive reads. This function uses TCR1 for the timebase. |

This function is available only on revision D and later of the MPC561 and is not available on revision B and earlier of the MPC563.

[Figure D-18](#) through [Figure D-21](#) show all of the host interface areas for the MULTI function.

| CONTROL BITS                                                                                                                                    |                                                                                                                        |                     |  |

## D.12 Fast Quadrature Decode TPU3 Function (FQD)

FQD is a position-feedback function for motor control. It provides the RCPU with a 16-bit free-running position counter by decoding the two signals from a slotted encoder. FQD incorporates a “speed switch” that disables one of the channels at high speed, allowing faster signals to be decoded. Furthermore, every counter update provides a time stamp that is useful for interpolating position and determining velocity at low speed or in instances that implement low-resolution encoders. The ITC function handles the third index channel provided by some encoders. See Freescale TPU Programming Note *Fast Quadrature Decode TPU Function (FQD)*, (TPUPN02/D).

[Figure D-22](#) and [Figure D-23](#) show the host interface areas for the FQD function for primary and secondary channels.

### D.13 Period/Pulse-Width Accumulator (PPWA)

The period/pulse-width accumulator (PPWA) algorithm accumulates a 16-bit or 24-bit sum of either the period or the pulse width of an input signal over a programmable number of periods or pulses (from one to 255). After an accumulation period, the algorithm can generate a link to a sequential block of up to eight channels. The user specifies a starting channel of the block and number of channels within the block. Generation of links depends on the mode of operation.

Any channel can be used to measure an accumulated number of periods of an input signal. A maximum of 24 bits can be used for the accumulation parameter. From one to 255 period measurements can be made and summed with the previous measurement(s) before the TPU3 interrupts the RCPU, allowing instantaneous or average frequency measurement, and the latest complete accumulation (over the programmed number of periods).

The pulse width (high-time portion) of an input signal can be measured (up to 24 bits) and added to a previous measurement over a programmable number of periods (one to 255). This provides an instantaneous or average pulse-width measurement capability, allowing the latest complete accumulation (over the specified number of periods) to always be available in a parameter.

By using the output compare function in conjunction with PPWA, an output signal can be generated that is proportional to a specified input signal. The ratio of the input and output frequency is programmable. One or more output signals with different frequencies, yet proportional and synchronized to a single input signal, can be generated on separate channels. See Freescale TPU Programming Note *Period/Pulse-Width Accumulator TPU Function (PPWA)*, (TPUPN11/D).

[Figure D-24](#) shows the host interface areas and parameter RAM for the PPWA function.

1. The TPU does not check the value of LINK\_CHANNEL\_COUNT. If this parameter is not >0 and < 8, results are unpredictable.

2. MAX\_COUNT may be written at any time by the host RCP, but if the value written is < PERIOD\_COUNT, a period or pulse-width accumulation is terminated. If this happens, the number of periods over which the accumulation is performed will not correspond to MAX\_COUNT.

## D.15 Output Compare (OC)

The output compare (OC) function generates a rising edge, falling edge, or a toggle of the previous edge: immediately upon RCPU initiation (generating a pulse with a length equal to a programmable delay time), after a programmable delay time, or continuously. Upon receiving a link from a channel, OC references, without RCPU interaction, a specifiable period and calculates an offset that is equal to the period  $\times$  the ratio, where the ratio is a supplied parameter.

This algorithm generates, with each high/low time, a 50% duty-cycle continuous square equal to the calculated offset. Due to offset calculation, there is an initial link time before continuous pulse generation begins. See Freescale TPU Programming Note *Output Compare TPU Function (OC)*, (TPUPN12/D).

[Figure D-26](#) shows the host interface areas and parameter RAM for the OC function.

## D.16 Pulse-Width Modulation (PWM)

The TPU3 can generate a pulse-width modulation (PWM) waveform with any duty cycle from 0 to 100% (within the resolution and latency capability of the TPU3). To define the PWM, the RCPU provides one parameter that indicates the period and another that indicates the high time. Updates to one or both of these parameters can effect waveform change immediately, or coherently at the next low-to-high pin transition. See Freescale TPU Programming Note *Pulse-Width Modulation TPU Function (PWM)*, (TPUPN17/D).

[Figure D-27](#) shows the host interface areas and parameter RAM for the PWM function.

## D.17 Discrete Input/Output (DIO)

The DIO function (Bank 0 and Bank 1) allows a TPU3 channel to be used as a digital I/O pin.

When a pin is used as a discrete input, a parameter indicates the current input level and the previous 15 levels of a pin. Bit 15, the most significant bit of the parameter, indicates the most recent state. Bit 14 indicates the next most recent state, and so on. The programmer can update the parameter when a transition occurs, when the RCPu makes a request, or when a rate specified in another parameter is matched.

When a pin is used as a discrete output, it is set high or low only upon request by the RCPu. See Freescale TPU Programming Note *Discrete Input/Output TPU Function (DIO)*, (TPUPN18/D).

[Figure D-28](#) shows the host interface areas for the DIO function.

## CONTROL BITS

See [Table 19-24](#) for the PRAM Address Offset Map.

**Figure D-28. DIO Parameters**

## D.18 Synchronized Pulse-Width Modulation (SPWM)

The SPWM function (Bank 0) generates a pulse-width modulated waveform (PWM). The RCPU can change the period or high time of the waveform at any time. Three different operating modes allow the function to maintain complex timing relationships between channels without RCPU intervention.

The SPWM output waveform duty cycle excludes 0% and 100%. If it is not necessary for a PWM to maintain a time relationship to another PWM, the PWM function should be used instead. See Freescale TPU Programming Note *Synchronized Pulse-Width Modulation TPU Function (SPWM)*, (TPUPN19/D).

[Figure D-29](#) shows all of the host interface areas for the SPWM function.

Figure D-29. SPWM Parameters (continued)

## D.19 Read/Write Timers and Pin TPU3 Function (RWTPIN)

The RWTPIN Bank 1 TPU3 function enables the RCPU to read, via locations in PRAM, both the TCR1 and TCR2 timer counters, and then selectively load TCR1 or TCR2 with a RCPU-supplied value contained in PRAM. The function also allows control of the pin state and direction of the RWTPIN channel.

A pin-state parameter is maintained in PRAM and is updated upon every service request. It can contain a value of the current pin state whether the pin is programmed as an input or output.

The function also receives links. Upon receipt, it will read the two TCRs into PRAM, updating the pin-state parameter and generating a maskable interrupt request to the RCPU.

The RCPU can control the channel pin, the TCRs, or both. To control the channel pin only, the ‘read TCR’ option is used and the values returned ignored. Because this function controls the TCRs without affecting the channel pin, it can run on a TPU3 channel whose pin is controlled by a function running on another channel (for example, a slave stepper-motor channel). See Freescale TPU Programming Note *Using The TPU Function Library And TPU Emulation Mode*, (TPUPN00/D).

Figure D-30 shows all of the host interface areas for the PTA function.

## D.20 Serial Input/Output Port (SIOP)

The serial input/output port (SIOP) TPU3 function uses two or three TPU3 channels to form a uni- or bidirectional synchronous serial port that can be used to communicate with a wide variety of devices. It can be used to add serial capabilities to a device without a serial port, or to extend the capabilities of one with a hardware-synchronous port. The SIOP TPU3 function has been designed to closely resemble the SIOP hardware port found on some Freescale MCUs.

SIOP operates in master mode (the TPU3 always generates the clock) and has the following programmable features:

1. Choice of one-channel clock-only, two-channel clock + transmit, two-channel clock + receive, or three-channel clock + transmit + receive operating modes
2. Freely programmable baud-rate period over a 15-bit range of TCR1 counts
3. Selection of MSB or LSB first shift direction
4. Variable transfer size from 1 to 16 bits
5. Programmable clock polarity

When a transfer of data is complete, the SIOP function notifies the host RCPU by issuing an interrupt request. The arrangement of the multiple SIOP channels is fixed: the data-out channel is the channel above the clock channel and the data-in channel is the channel below the clock channel. In clock-only or uni-directional mode, the unused TPU3 channels are free to run other TPU3 functions. Two possible SIOP configurations are shown in [Figure D-31](#)

**Figure D-31. Two Possible SIOP Configurations**

### D.20.1 Parameters

[Figure D-32](#) shows the host interface areas and parameter RAM for the SIOP function. The following sections describe these parameters.

**NOTE**

Only the clock channel requires any programming. The data-in and data-out channels are entirely under TPU3 microcode control.

Figure D-32. SIOP Parameters

## CONTROL BITS

See [Table 19-24](#) for the PRAM Address Offset Map.

**Figure D-32. SIOP Parameters**

### D.20.1.1 CHAN\_CONTROL

This 9-bit, RCPU-written parameter is used to set up the clock polarity for the SIOP data transfer. The valid values for CHAN\_CONTROL for this function are given in [Table D-3](#). CHAN\_CONTROL must be written by the host before issuing the host service request (HSR) to initialize the function.

**Table D-3. SIOP Function Valid CHAN\_Control Options**

| CHAN_CONTROL <sup>1</sup><br>8 7 6 5 4 3 2 1 0 | Resulting Action                  |
|------------------------------------------------|-----------------------------------|
| 0 1 0 0 0 1 1 0 1                              | Data valid on clock Falling edge. |
| 0 1 0 0 0 1 1 1 0                              | Data valid on clock Rising edge.  |

<sup>1</sup> Other values of CHAN\_CONTROL may result in indeterminate operation.

### D.20.1.2 BIT\_D

BIT\_D is a RCPU-written bit that determines the direction of shift of the SIOP data. If BIT\_D is zero, then SIOP\_DATA is right shifted (LSB first). If BIT\_D is one then SIOP\_DATA is left shifted (MSB first).

### D.20.1.3 HALF\_PERIOD

This RCPU-written parameter defines the baud rate of the SIOP function. The value contained in HALF\_PERIOD is the number of TCR1 counts for a half-SIOP clock period (for example, for a 50 baud rate, with a TCR1 period of 240 ns, the value  $[(1/50)/2]/240 \text{ ns} = 42$ ) should be written to HALF\_PERIOD. The range for HALF\_PERIOD is 1 to 0x8000, although the minimum value in practice will be limited by other system conditions. See the notes in [Section D.20.1.6, “SIOP\\_DATA”](#) for information on the use and performance of the SIOP function.

### D.20.1.4 BIT\_COUNT

The TPU3 uses this parameter to count down the number of bits remaining during a transfer in progress. During the SIOP initialization state, BIT\_COUNT is loaded with the value contained in XFER\_SIZE and then decremented as the data is transferred. When it reaches zero, the transfer is complete and the TPU3 issues an interrupt request to the RCPU.

### D.20.1.5 XFER\_SIZE

This RCPU-written parameter determines the number of bits that make up a data transfer. During initialization, XFER\_SIZE is copied into BIT\_COUNT. XFER\_SIZE is shown as a 5-bit parameter to match the maximum size of 16 bits in SIOP\_DATA, although the TPU3 uses the whole word location. For normal use, XFER\_SIZE should be in the 1- to 16-bit range.

### D.20.1.6 SIOP\_DATA

This parameter is the data register for all SIOP transfers. Data is shifted out of one end of SIOP\_DATA and shifted in at the other end, the shift direction being determined by the value of BIT\_D. In output-only mode, zero will be shifted into SIOP\_DATA and in input-only mode, the data shifted out is ignored. In clock-only mode, SIOP\_DATA is still shifted.

#### NOTE

The TPU3 does not “justify” the data position in SIOP\_DATA (for example, if an 8-bit bidirectional transfer is made, shifting LSB first, then the bottom byte of SIOP\_DATA will be shifted out and the input data will be shifted into the upper byte of SIOP\_DATA).

#### NOTE

SIOP\_DATA is not buffered. The RCPU should only access it between completion of one transfer and the start of the next.

## D.20.2 Host RCPU Initialization of the SIOP Function

The RCPU initializes the SIOP function by:

1. Disabling the channel by clearing the two channel-priority bits
2. Selecting the SIOP function on the channel by writing the assigned SIOP function number to the function-select bits
3. Writing CHAN\_CONTROL in the clock channel parameter RAM
4. Writing HALF\_PERIOD, BIT\_D, and XFER\_SIZE in the clock-channel parameter RAM to determine the speed, shift direction, and size of the transfer
5. Writing SIOP\_DATA if the data output is to be used
6. Selecting the required operating mode via the two host-sequence bits
7. Issuing a host service request type 0b11
8. Enabling service by assigning H, M, or L priority to the clock channel via the two channel-priority bits

The TPU3 then starts the data transfer, and issues an interrupt request when the transfer is complete.

Once the function has been initialized, the RCPU only needs to write SIOP\_DATA with the new data and issue a HSR 0b11 to initiate a new transfer. In input-only or clock-only modes, just the HSR 0b11 is required.

## D.20.3 SIOP Function Performance

Like all TPU3 functions, the performance limit of the SIOP function depends, because of the operational nature of the scheduler, on the service time (latency) associated with other active TPU3 channels. Where two channels are used for a uni-directional system and no other TPU3 channels are active, the maximum baud rate is approximately 230 at a bus speed of 16.77 MHz. A three-channel bidirectional system under the same conditions has a maximum baud rate of approximately 200. When more TPU3 channels are

active, these performance figures will be degraded; however, the scheduler assures that the worst-case latency in any TPU3 application can be closely approximated. TPU3 reference manual guidelines and information given in the SIOP-state timing table should be used to perform an analysis on any proposed TPU3 application that appears to approach the TPU's performance limits.

**Table D-4. SIOP State Timing<sup>1</sup>**

| State Number and Name          | Max. RCPU Clock Cycles | Number of RAM Accesses by TPU3 |
|--------------------------------|------------------------|--------------------------------|
| S1 SIOP_INIT<br>HSQ = X0<br>X1 | 28<br>38               | 7<br>7                         |
| S2 DATA_OUT<br>HSQ = X0<br>X1  | 14<br>24               | 4<br>4                         |
| S3 DATA_IN<br>HSQ = 0X<br>1X   | 14<br>28               | 4<br>6                         |

<sup>1</sup> Execution times do not include the time slot transition time (TST = 10 or 14 RCPU clocks).

### D.20.3.1 XFER\_SIZE Greater Than 16

XFER\_SIZE is normally programmed to be in the 1- to 16-bit range to match the size of SIOP\_DATA, and has thus been shown as a 5-bit value in the host interface diagram. However, the TPU3 actually uses all 16 bits of the XFER\_SIZE parameter when loading BIT\_COUNT. In some unusual circumstances this can be used to an advantage. If an input device is producing a data stream of greater than 16 bits then manipulation of XFER\_SIZE will allow selective capturing of the data. In clock-only mode, the extended XFER\_SIZE can be used to generate up to 0xFFFF clocks.

### D.20.3.2 Data Positioning

As stated above, the TPU3 does not “justify” the data position in SIOP\_DATA. Therefore, in the case of a byte transfer, the data output will be sourced from one byte and the data input will shift into the other byte. This is true for all data sizes except 16 bits, in which case the full SIOP\_DATA register is used for both data output and input.

### D.20.3.3 Data Timing

In the example given in [Figure D-33](#), the data output transitions are shown as being completely synchronous with the relevant clock edge and it is assumed that the data input is latched exactly on the opposite clock edge. This is the simplest way to show the examples, but is not strictly true. Since the TPU3 is a multi-tasking system, and the data channels are manipulated directly by microcode software while servicing the clock edge, there is a finite delay between the relevant clock edge and the data-out being valid or the data-in being latched. This delay is equivalent to the latency in servicing the clock channel due to other TPU3 activity and is shown as ‘Td’ in the timing diagram. Td is the delay between the clock edge and the next output data being valid and also the delay between the opposite clock edge and the input data being read. For the vast majority of applications, the delay Td will not present a problem and can be ignored. Only for a system which heavily loads the TPU3 should the worst case latency be calculated for

the SIOP clock channel + actual SIOP service time ( $= T_d$ ) and ensure that the baud rate is chosen such that  $\text{HALF\_PERIOD} - T_d$  is not less than the minimum setup time of the receiving device. A transmitting device must also hold data valid for a minimum time of  $T_d$  after the clock.

Figure D-33. SIOP Function Data Transition Example

# Appendix E

## Memory Access Timing

**Table E-1** lists all possible memory access timings for internal and external memory combinations. The clock values show the number of clocks from the moment an address is valid on a specific bus, until data is back on that same bus. The following assumptions were used when compiling the information:

- The arbitration time was ignored. The values assume that the bus (or buses) involved in a transaction was in the IDLE state when the transaction needs that bus.
- The UIMB works in a mode of 1:1. This is relevant for IMB access values. In the case of 2:1 mode, the clock latency for a cycle on the IMB should be doubled (each IMB access takes two clocks).
- The basic delay of an external bus to a U-bus is four clocks (external master case).
- All IMB accesses are assumed to be 16-bit accesses only. If 32-bit accesses are used, then each such IMB access is split into two separate 16-bit cycles with normal IMB performance for each.

**Table E-1. Memory Access Times Using Different Buses**

|                                                               | Internal Buses   |                |            |     |                | External RAM/Flash                       |                                  | Show Cycle |                |

<sup>1</sup> N is the number of read cycle clocks from external address valid until external data valid. In the case of zero wait states, N = 2.

<sup>2</sup> Core instruction fetch data bus is usually the U-bus

<sup>3</sup> 8 clocks are dedicated for external accesses, and internal accesses are denied.

<sup>4</sup> Assuming the external master immediately retries

**Note:** Shaded areas = address phase ; Non-shaded areas = data phase

## Appendix F

### Electrical Characteristics

This appendix contains detailed information on power considerations, DC/AC electrical characteristics, and AC timing characteristics of the MPC561/MPC563. The MPC561/MPC563 is designed to operate at 40 MHz, or optionally at 56 or 66 MHz. Refer to [Appendix G, “66-MHz Electrical Characteristics,”](#) for more information.

**Table F-1. Absolute Maximum Ratings (VSS = 0V)**

| 21  | Junction Temperature Range                                                                   | T <sub>J</sub>                     | -40                   | +150                   | °C   |
| 22  | Storage Temperature Range                                                                    | T <sub>STG</sub>                   | -55                   | +150                   | °C   |
| 23  | Maximum Solder Temperature <sup>15</sup>                                                     | T <sub>SDR</sub>                   | —                     | 235                    | °C   |
| 24  | Moisture Sensitivity Level <sup>16</sup>                                                     | MSL                                | —                     | 3                      | —    |

- <sup>1</sup> For internal digital supply of  $V_{DDL} = 2.6\text{-V}$  typical.
- <sup>2</sup> 2.6 volt supply pins can withstand up to 3.6 volts for acumulative time of 24 hours over the lifetime of the device.
- <sup>3</sup> During operation the value of  $V_{FLASH}$  must be  $5.0\text{ V} \pm 5\%$
- <sup>4</sup> These power supplies are available on MPC563 and MPC564 only.
- <sup>5</sup> Maximum average current into the IRAMSTBY pin must be  $< 1.75\text{mA}$ .
- <sup>6</sup>  $V_{DDA} = 5.0\text{ V} \pm 5\%$ .
- <sup>7</sup> All 2.6-V input-only pins are 5-V tolerant.
- <sup>8</sup> Note that long term reliability may be compromised if 2.6-V output drivers drive a node which has been previously pulled to  $>3.1\text{ V}$  by an external component.  $\overline{\text{HRESET}}$  and  $\overline{\text{SRESET}}$  are fully 5-V compatible.
- <sup>9</sup> 6.35 V on 5-V only pins (all QADC, all TPU, all QSMCM and the following MIOS pins: MDA[11:15], MDA[27:31], MPWM16, MPIO32B[7:9]/MPWM[20:21], MPIO32B11/C\_CNRX0, MPIO32B12/C\_CNTX0). Internal structures hold the input voltage below this maximum voltage on all of these pins, except the QSMCM RXD1/QPI1 and RXD2/QPI2/C\_CNRX0 pins, if the maximum injection current specification is met (1 mA for all pins; exception: 3 mA on QADC pins) and VDDH is within Operating Voltage specifications (see specification 43 in [Table F-4](#)). Exception: The RXD1/QGPI1 and RXD2/GPI2 pins do not have clamp diodes to VDDH. Voltage must be limited to less than 6.5 volts on these 2 pins to prevent damage.
- <sup>10</sup> Maximum continuous current on I/O pins provided the overall power dissipation is below the power dissipation of the package. Proper operation is not guaranteed at this condition.
- <sup>11</sup> Condition applies to one pin at a time.
- <sup>12</sup> Transitions within the limit do not affect device reliability or cause permanent damage. Exceeding limit may cause permanent conversion error on stressed channels and on unstressed channels.
- <sup>13</sup> Maximum transient current per ISO7637.
- <sup>14</sup> Maximum operating temperature on any solder ball in outer four rows of solder balls on the package. These rows are referred to as "Perimeter Balls" to distinguish them from the balls in the center of the package.
- <sup>15</sup> Solder profile per CDF-AEC-Q100, current revision.
- <sup>16</sup> Moisture sensitivity per JEDEC test method J-STD-020-A (April 1999).

Functional operating conditions are given in [Section F.5, "DC Electrical Characteristics."](#) Absolute maximum ratings are stress ratings only, and functional operation at the maximum is not guaranteed. Stress beyond those listed may affect device reliability or cause permanent damage to the device.

This device contains circuitry protecting against damage due to high static voltage or electrical fields; however, it is advised that normal precautions be taken to avoid application of any voltages higher than maximum-rated voltages to this high-impedance circuit. Reliability of operation is enhanced if unused inputs are tied to an appropriate logic voltage level (e.g., either  $V_{SS}$  or  $V_{DD}$ ).

## NOTE

Negative current flows out of the pin and positive current flows into the pin.

## F.1 Package

The MPC561/MPC563 is available in packaged form. The package is a 388-ball PBGA having a 1.0 mm ball pitch, Freescale case outline 1164-01 (See [Figure F-64](#) and [Figure F-65](#)).

## F.2 EMI Characteristics

### F.2.1 Reference Documents

The document referenced for the EMC testing of MPC561/MPC563 is SAE J1752/3 Issued 1995-03

## F.2.2 Definitions and Acronyms

EMC – Electromagnetic Compatibility

EMI – Electromagnetic Interference

TEM cell – Transverse Electromagnetic Mode cell

## F.2.3 EMI Testing Specifications

1. Scan range: 150 KHz – 1000 MHz
2. Operating Frequency: 56 MHz
3. Operating Voltages: 2.6 V, 5.0 V
4. Max spikes: TBD dBuV
5. I/O port waveforms: Per J1752/3
6. Temperature: 25 °C

## F.3 Thermal Characteristics

**Table F-2. Thermal Characteristics**

| Characteristic                                                                                    | Symbol           | Value                 | Unit |
|---------------------------------------------------------------------------------------------------|------------------|-----------------------|------|
| BGA Package Thermal Resistance, Junction to Ambient – Natural Convection                          | $R_{\theta JA}$  | 47.3 <sup>1,2,3</sup> | °C/W |
| BGA Package Thermal Resistance, Junction to Ambient – Four layer (2s2p) board, natural convection | $R_{\theta JMA}$ | 29.4 <sup>3,4,5</sup> | °C/W |
| BGA Package Thermal Resistance, Junction to Board                                                 | $R_{\theta JB}$  | 21.2 <sup>3,6</sup>   | °C/W |
| BGA Package Thermal Resistance, Junction to Case (top)                                            | $R_{\theta JT}$  | 7.0 <sup>3,7</sup>    | °C/W |
| BGA Package Thermal Resistance, Junction to Package Top, Natural Convection                       | $\Psi_{JT}$      | 1.6 <sup>8</sup>      | °C/W |

<sup>1</sup> Junction temperature is a function of on-chip power dissipation, package thermal resistance, mounting site (board) temperature, ambient temperature, air flow, power dissipation of other components on the board, and the board thermal resistance.

<sup>2</sup> Per SEMI G38-87 and JESD51-2 with the board horizontal.

<sup>3</sup> These values are the mean + 3 standard deviations of characterized data.

<sup>4</sup> Junction temperature is a function of on-chip power dissipation, package thermal resistance, mounting site (board) temperature, ambient temperature, air flow, power dissipation of other components on the board, and the board thermal resistance.

<sup>5</sup> Per JESD51-6 with the board horizontal.

<sup>6</sup> Thermal resistance between the die and the printed circuit board (Four layer (2s2p) board, natural convection).

<sup>7</sup> Indicates the thermal resistance between the die and the case top surface as measured by the cold plate method (MIL SPEC-883 Method 1012.1) with the cold plate temperature used for the case temperature.

<sup>8</sup> Thermal characterization parameter indicating the temperature difference between package top and the junction temperature per EIA/JESD51-2.

An estimation of the chip junction temperature,  $T_J$ , in  $^{\circ}\text{C}$  can be obtained from the equation:

$$T_J = T_A + (R_{\theta JA} \times P_D)$$

where:

$T_A$  = ambient temperature ( $^{\circ}\text{C}$ )

$R_{\theta JA}$  = package junction to ambient resistance ( $^{\circ}\text{C}/\text{W}$ )

$P_D$  = power dissipation in package

The junction to ambient thermal resistance is an industry standard value which provides a quick and easy estimation of thermal performance. Unfortunately, the answer is only an estimate; test cases have demonstrated that errors of a factor of two are possible. As a result, more detailed thermal characterization is supplied.

Historically, the thermal resistance has frequently been expressed as the sum of a junction to case thermal resistance and a case to ambient thermal resistance:

$$R_{\theta JA} = R_{\theta JC} + R_{\theta CA}$$

where:

$R_{\theta JA}$  = junction to ambient thermal resistance ( $^{\circ}\text{C}/\text{W}$ )

$R_{\theta JC}$  = junction to case thermal resistance ( $^{\circ}\text{C}/\text{W}$ )

$R_{\theta CA}$  = case to ambient thermal resistance ( $^{\circ}\text{C}/\text{W}$ )

$R_{\theta JC}$  is device related and cannot be influenced. The user controls the thermal environment to change the case to ambient thermal resistance,  $R_{\theta CA}$ . For instance, the air flow can be changed around the device, add a heat sink, change the mounting arrangement on printed circuit board, or change the thermal dissipation on the printed circuit board surrounding the device. This description is most useful for ceramic packages with heat sinks where about 90% of the heat flow is through the case to the heat sink to ambient. For most packages, a better model is required.

The simplest thermal model of a package which has demonstrated reasonable accuracy (about 20 percent) is a two resistor model consisting of a junction to board and a junction to case thermal resistance. The junction to case covers the situation where a heat sink will be used or where a substantial amount of heat is dissipated from the top of the package. The junction to board thermal resistance describes the thermal performance when most of the heat is conducted to the printed circuit board. It has been observed that the thermal performance of most plastic packages and especially PBGA packages is strongly dependent on the board temperature.

If the board temperature is known, an estimate of the junction temperature in the environment can be made using the following equation:

$$T_J = T_B + (R_{\theta JB} \times P_D)$$

where:

$T_B$  = board temperature ( $^{\circ}\text{C}$ )

$R_{\theta JB}$  = package junction to board resistance ( $^{\circ}\text{C}/\text{W}$ )

$P_D$  = power dissipation in package ( $\Omega$ )

If the board temperature is known and the heat loss from the package case to the air can be ignored, acceptable predictions of junction temperature can be made. For this method to work, the board and board mounting must be similar to the test board used to determine the junction to board thermal resistance, namely a 2s2p (board with a power and a ground plane) and vias attaching the thermal balls to the ground plane.

When the board temperature is not known, a thermal simulation of the application is needed. The simple two-resistor model can be used with the thermal simulation of the application (2), or a more accurate and complex model of the package can be used in the thermal simulation. Consultation on the creation of the complex model is available.

To determine the junction temperature of the device in the application after prototypes are available, the thermal characterization parameter ( $\Psi_{JT}$ ) can be used to determine the junction temperature with a measurement of the temperature at the top center of the package case using the following equation:

$$T_J = T_T + (\Psi_{JT} \times P_D)$$

where:

$T_T$  = thermocouple temperature on top of package (°C)

$\Psi_{JT}$  = thermal characterization parameter

$P_D$  = power dissipation in package

The thermal characterization parameter is measured per JESD51-2 specification published by JEDEC using a 40 gauge type-T thermocouple epoxied to the top center of the package case. The thermocouple should be positioned so that the thermocouple junction rests on the package. A small amount of epoxy is placed over the thermocouple junction and over about one mm of wire extending from the junction. The thermocouple wire is placed flat against the package case to avoid measurement errors caused by cooling effects of the thermocouple wire.

## F.4 ESD Protection

**Table F-3. ESD Protection**

| Characteristics                             | Symbol | Value | Units    |
|---------------------------------------------|--------|-------|----------|
| ESD for Human Body Model (HBM) <sup>1</sup> |        | 2000  | V        |
| HBM Circuit Description                     | R1     | 1500  | $\Omega$ |
|                                             | C      | 100   | pF       |
| ESD for Machine Model (MM)                  |        | 200   | V        |
| MM Circuit Description                      | R1     | 0     | $\Omega$ |
|                                             | C      | 200   | pF       |
| Number of pulses per pin <sup>2</sup>       |        |       | —        |
| Positive pulses (MM)                        | —      | 3     |          |
| Negative pulses (MM)                        | —      | 3     |          |
| Positive pulses (HBM)                       | —      | 1     |          |
| Negative pulses (HBM)                       | —      | 1     |          |
| Interval of Pulses                          | —      | 1     | S        |

<sup>1</sup> All ESD testing is in conformity with CDF-AEC-Q100 Stress Test Qualification for Automotive Grade Integrated Circuits.

<sup>2</sup> A device will be defined as a failure if after exposure to ESD pulses the device no longer meets the device specification requirements. Complete DC parametric and functional testing shall be performed per applicable device specification at room temperature followed by hot temperature, unless specified otherwise in the device specification.

## F.5 DC Electrical Characteristics

**Note:** ( $V_{DD} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{DDH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ )

**Table F-4. DC Electrical Characteristics**

| 57  | Power Dissipation – 56 MHz<br>40 MHz                                                                                                                           | PD                                |                     | 1.12<br>0.8 | W<br>W   |

<sup>1</sup> This characteristic is for 2.6-V output and 5-V input friendly pins.

<sup>2</sup> VDATAPC is the maximum voltage the data pins can have been precharged to by an external device when the MPC561/MPC563 data pins turn on as outputs. The 3.1-V maximum for VDATAPC is to allow the data pins to be driven from an external memory running at a higher voltage. Note that if the data pins are precharged to higher than  $V_{DDL}$ , then the 50-pF maximum load characteristic must be observed.

<sup>3</sup> The predischage circuit is enabled by setting the PREDIS\_EN bit to a “1” in the PDMCR2 register. VDATAPC is the maximum voltage the data pins can have been precharged to by an external device when the MPC561/MPC563 data pins turn on as outputs. The 5.25-V maximum for VDATAPC is to allow the data pins to be driven from an external memory running at a higher voltage. Note that if the data pins are precharged to higher than  $V_{DDL}$ , then the maximum load characteristic must match the data bus drive setting and the data bus can withstand up to 3.6 volts for a cumulative time of 24 hours over the lifetime of the device.

<sup>4</sup> This characteristic is for 5-V output and 5-V input pins.

<sup>5</sup>  $0.3V > V_{DDA}$  or  $V_{DDH}$ , whichever is greater.

<sup>6</sup> Within this range, no significant injection will be seen. See QADC64 Disruptive Input Current ( $I_{NA}$ ).

<sup>7</sup> During reset all 2.6V and 2.6V/5V pads will leak up to 10 $\mu$ A to QVDDL if the pad has a voltage > QVDDL.

<sup>8</sup> Maximum leakage occurs at maximum operating temperature. Current decreases by approximately one-half for each 8 to 12 °C, in the ambient temperature range of 50 to 125 °C.

<sup>9</sup> All bus pins support two drive strengths capabilities, 25 pF and 50 pF. Current drive is less at the 25-pF capacitive load. Both modes achieve 40-MHz (or, optionally, 56-MHz) timing.

<sup>10</sup> Only IRQ, TPU, MIOS, GPIO, QADC (when digital inputs) and RESET pins have hysteresis, thus there is no hysteresis specification on all other pins

<sup>11</sup> Values to be characterized. Current consumption values will be updated as information becomes available. Initial values are only estimates based on predicted capacitive differences between CDR1 and CDR3 as well as actual CDR1 measurements.

<sup>12</sup> All power consumption specifications assume 50-pF loads and running a typical application. The power consumption of some modules could go up if they are exercised heavier, but the power consumption of other modules would decrease.

<sup>13</sup> This value depends on the R value set by the user. Refer to [Appendix C, “Clock and Board Guidelines.”](#)

<sup>14</sup> These power supplies are available on the MPC563 and MPC564 only.

<sup>15</sup> Current measured at maximum system clock frequency with QADC active.

<sup>16</sup> Transient currents can reach 50mA.

<sup>17</sup> KAPWR and IRAMSTBY can be powered-up prior to any other supply or at the same time as the other 2.6 V supplies. IRAMSTBY must lead or coincide with VDD; however it can lag KAPWR.

- <sup>18</sup> This parameter is periodically sampled rather than 100% tested
- <sup>19</sup> Up to 0.5 V during power up/down.
- <sup>20</sup> To obtain full-range results,  $V_{SSA} \leq V_{RL} \leq V_{INDC} \leq V_{RH} \leq V_{DDA}$
- <sup>21</sup> When using the QADC in legacy mode it is recommended to connect this pin to 2.6V or 3.3V, however it can be connected to 0V or 5V without damage to the device.
- <sup>22</sup> A resistor must be placed in series with the IRAMSTBY power supply. Refer to [Appendix C, "Clock and Board Guidelines."](#)
- <sup>23</sup> All injection current is transferred to the  $V_{DDH}$ . An external load is required to dissipate this current to maintain the power supply within the specified voltage range.
- <sup>24</sup> Absolute maximum voltage ratings for each pin (see [Table F-1](#)) must also be met during this condition.
- <sup>25</sup> Total injection current for all I/O pins on the chip must not exceed 20 mA (sustained current). Exceeding this limit can cause disruption of normal operation.
- <sup>26</sup> Current refers to two QADC64 modules operating simultaneously.
- <sup>27</sup> Below disruptive current conditions, the channel being stressed has conversion values of 0x3FF for analog inputs greater than  $V_{RH}$  and 0x000 for values less than  $V_{RL}$ . This assumes that  $V_{RH} \leq V_{DDA}$  and  $V_{RL} \geq V_{SSA}$  due to the presence of the sample amplifier. Other channels are not affected by non-disruptive conditions.

## F.6 Oscillator and PLL Electrical Characteristics

**Note:** ( $V_{DD} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{DDH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ )

| Array P/E Cycles <sup>1</sup>        | Maximum number of Program/Erase cycles per block to guarantee data retention.                                                               | 1,000                                                  |
| CENSOR Set/Clear Cycles <sup>2</sup> | Minimum number of Program/Erase cycles per bit before failure.                                                                              | 100                                                    |
| Array and CENSOR Data Retention      | Minimum data retention at an average of 85 °C junction temperature.<br>Minimum data retention at an average of 125 °C junction temperature. | Min 15 years <sup>3</sup><br>Min 10 years <sup>3</sup> |

<sup>1</sup> A Program/Erase cycle is defined as switching the bits from 1 to 0 to 1.

<sup>2</sup> A CENSOR Set/Clear cycle is defined as switching the bits from 1 to 0 to 1.

<sup>3</sup> Maximum total time @ 150 °C junction temperature  $\leq 1$  year.

## F.8 Power-Up/Down Sequencing

The supply symbols used in this section are described in [Table F-9](#).

**Table F-9. Power Supply Pin Groups**

| Symbol                                                                  | Types of Power Pins                                                        |
|-------------------------------------------------------------------------|----------------------------------------------------------------------------|
| V <sub>DDH</sub><br>(High Voltage Supply Group)                         | Supply to the 5-V pads for output driver (V <sub>DDH</sub> )               |
|                                                                         | Supply to the analog (QADC64E) circuitry (V <sub>DDA</sub> )               |
|                                                                         | High voltage supply to the flash module (V <sub>FLASH</sub> ) <sup>1</sup> |
| V <sub>DDL</sub><br>(Low Voltage Supply Pins)                           | Supply to low voltage pad drivers (QVDDL, NVDDL)                           |
|                                                                         | Supply to all low voltage internal logic (V <sub>DD</sub> )                |
|                                                                         | Supply to low voltage flash circuitry (V <sub>DDF</sub> ) <sup>1</sup>     |
|                                                                         | Supply to system PLL                                                       |
| V <sub>DDKA</sub><br>(Low Voltage Keep-Alive Supply Pins <sup>2</sup> ) | Supply to IRAMSTBY                                                         |
|                                                                         | Supply to oscillator and other circuitry for keep-alive functions (KAPWR). |

<sup>1</sup> These power supplies are only available on the MPC563 and MPC564.

<sup>2</sup> Any supply in the V<sub>DDKA</sub> group can be powered with the V<sub>DDL</sub> if the function which it supplies is not required during “Keep-alive.”

There are two power-up/down options. Choosing which one is required for an application will depend upon circuitry connected to 2.6-V compliant pins and dual 2.6-V/5-V compliant pins. Power-up/down option A is required if 2.6-V compliant pins and dual 2.6-V/5-V compliant pins are connected to the 5-V supply with a pull-up resistor or driven by 5-V logic during power-up/down. In applications for which this scenario is not true the power-up/down option B may be implemented. Option B is less stringent and easier to ensure over a variety of applications.

Refer to [Table 2-1](#) for a list of 2.6 V and dual 2.6V/5 V compliant pins.

The power consumption during power-up/down sequencing will stay below the operating power consumption specifications when following these guidelines.

### NOTE:

The V<sub>DDH</sub> ramp voltage should be kept below 50V/ms and the V<sub>DDL</sub> ramp rate less than 25V/ms.

### F.8.1 Power-Up/Down Option A

The Option A power-up sequence (excluding V<sub>DDKA</sub>) is

1.  $V_{DDH} \leq V_{DDL} + 3.1 \text{ V}$  (V<sub>DDH</sub> cannot lead V<sub>DDL</sub> by more than 3.1 V)
2.  $V_{DDH} \geq V_{DDL} - 0.5 \text{ V}$  (V<sub>DDH</sub> cannot lag V<sub>DDL</sub> by more than 0.5 V)

The first step in the sequence is required is due to gate-to-drain stress limits for transistors in the pads of 2.6-V compliant pins and dual 2.6-V/5-V compliant pins. Damage can occur if gate-to-drain voltage potential is greater than 3.1 V. This is only a concern at power-up/down. The second step in the sequence

is required is due to ESD diodes in the pad logic for dual 2.6-V/5-V compliant pins and 2.6-V pins. The diodes are forward biased when  $V_{DDL}$  is greater than  $V_{DDH}$  and will start to conduct current.

Figure F-1 illustrates the power-up sequence if no keep-alive supply is required. Figure F-2 illustrates the power-up sequence if a keep-alive supply is required. The keep-alive supply should be powered-up at the same instant or before both the high voltage and low voltage supplies are powered-up.

$V_{DDH}$  cannot lead  $V_{DDL}$  by more than 3.1 V  
 $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V

**Figure F-1. Option A Power-Up Sequence Without Keep-Alive Supply**

$V_{DDH}$  cannot lead  $V_{DDL}$  by more than 3.1 V  
 $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V

**Figure F-2. Option A Power-Up Sequence With Keep-Alive Supply**

The option A power-down sequence (excluding  $V_{DDKA}$ ) is

1.  $V_{DDH} \leq V_{DDL} + 3.1 \text{ V}$  ( $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 3.1 V)
2.  $V_{DDH} \geq V_{DDL} - 0.5 \text{ V}$  ( $V_{DDH}$  cannot lead  $V_{DDL}$  by more than 0.5 V)

Figure F-3 illustrates the power-down sequence if no keep-alive supply is required.

**Figure F-3. Option A Power-Down Sequence Without Keep-Alive Supply**

Figure F-4 illustrates the power-down sequence if a keep-alive supply is required.

**Figure F-4. Option A Power-Down Sequence With Keep-Alive Supply**

## F.8.2 Power-Up/Down Option B

A less stringent power-up sequence may be implemented if 2.6-V compliant pins and dual 2.6-V/5-V compliant pins are NOT connected to the 5-V supply with a pull-up resistor or driven by 5-V logic during power-up/down.

The option B power-up sequence (excluding  $V_{DDKA}$ ) is:

1.  $V_{DDH} > V_{DDL} - 0.5 \text{ V}$  ( $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V)

Thus the  $V_{DDH}$  supply group can be fully powered-up prior to power-up of the  $V_{DDL}$  supply group, with no adverse affects to the device.

The requirement that  $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V is due to ESD diodes in the pad logic for dual 2.6-V/5-V compliant pins and 2.6-V pins. The diodes are forward biased when  $V_{DDL}$  is greater than  $V_{DDH}$  and will start to conduct current.

Figure F-5 illustrates the power-up sequence if no keep-alive supply is required. Figure F-6 illustrates the power-up sequence if a keep-alive supply is required. The keep-alive supply should be powered-up at the same time or before both the high voltage and low voltage supplies are powered-up.

**Figure F-5. Option B Power-Up Sequence Without Keep-Alive Supply**

**Figure F-6. Option B Power-Up Sequence With Keep-Alive Supply**

The option B power-down sequence (excluding  $V_{DDKA}$ ) is:

1. The  $V_{DDL}$  supply group can be fully powered-down prior to power-down of the  $V_{DDH}$  supply group, with no adverse affects to the device.

For power-down, the low voltage supply should come down before the high voltage supply, although with varying loads, the high voltage may actually get ahead.

Figure F-7 illustrates the power-down sequence if no keep-alive supply is required. Figure F-8 illustrates the power-down sequence if a keep-alive supply is required.

Figure F-7. Option B Power-Down Sequence Without Keep-Alive Supply

Figure F-8. Option B Power-Down Sequence with Keep-Alive Supply

## F.9 Issues Regarding Power Sequence

### F.9.1 Application of $\overline{\text{PORESET}}$ or $\overline{\text{HRESET}}$

When  $V_{DDH}$  is rising and  $V_{DDL}$  is at 0.0 V, as  $V_{DDH}$  reaches 1.6 V, all 5 V drivers are tristated. Before  $V_{DDH}$  reaches 1.6V, all 5 V outputs are unknown. If  $V_{DDL}$  is rising and  $V_{DDH}$  is at least 3.1 V greater than  $V_{DDL}$ , then the 5 V drivers can come out of tristate when  $V_{DDL}$  reaches 1.1 V, and the 2.6 V drivers can start driving when  $V_{DDL}$  reaches 0.5 V. For these reasons, the  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  signal must be asserted during power-up before  $V_{DDL}$  is above 0.5 V.

If the  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  signal is not asserted before this condition, there is a possibility of disturbing the programmed state of the flash. In addition, the state of the pads are indeterminant until  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  propagates through the device to initialize all circuitry.

## F.9.2 Keep-Alive RAM

$\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  must be asserted during power-down prior to any supply dropping out of specified operating conditions.

An additional constraint is placed on  $\overline{\text{PORESET}}$  assertion since it is an asynchronous input. To assure that the assertion of  $\overline{\text{PORESET}}$  does not potentially cause stores to keep-alive RAM to be corrupted (store single or store multiple) or non-coherent (store multiple), either of the following solutions is recommended:

- Assert  $\overline{\text{HRESET}}$  at least 0.5  $\mu\text{s}$  prior to when  $\overline{\text{PORESET}}$  is asserted.
- Assert  $\overline{\text{IRQ0}}$  (non-maskable interrupt) at least 0.5  $\mu\text{s}$  prior to when  $\overline{\text{PORESET}}$  is asserted. The service routine for  $\overline{\text{IRQ0}}$  should not perform any writes to keep-alive RAM.

The amount of delay that should be added to  $\overline{\text{PORESET}}$  assertion is dependent upon the frequency of operation and the maximum number of store multiples executed that are required to be coherent. If store multiples of more than 28 registers are needed and if the frequency of operation is lower than 56 MHz, the delay added to  $\overline{\text{PORESET}}$  assertion will need to be greater than 0.5  $\mu\text{s}$ . In addition, if KAPWR features are being used,  $\overline{\text{PORESET}}$  should not be driven low while the  $V_{\text{DDH}}$  and  $V_{\text{DDL}}$  supplies are off.

## F.10 AC Timing

Figure F-9 displays generic examples of MPC561/MPC563 timing. Specific timing diagrams are shown in Figure F-10 through Figure F-36.

Figure F-9. Generic Timing Examples

**Table F-10. Bus Operation Timing**

**Note:** ( $V_{DD} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{DDH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ , 50 pF load unless noted otherwise)

|    | Characteristic                                                                                                                                                                     | 40 MHz    |            | 56 MHz <sup>1</sup> |            | Unit |

| 30 | CLKOUT Rising Edge to $\overline{TS}$ Valid (Hold Time). | 5      |     | 5                   |     | ns   |

<sup>1</sup> 56-MHz operation is available as an option. Some parts (without the 56-MHz option) will operate at a maximum frequency of 40 MHz.

<sup>2</sup> The timing for  $\overline{BR}$  output is relevant when the MPC561/MPC563 is selected to work with external bus arbiter. The timing for  $\overline{BG}$  output is relevant when the MPC561/MPC563 is selected to work with internal bus arbiter.

<sup>3</sup> The setup times required for  $\overline{TA}$ ,  $\overline{TEA}$ , and  $\overline{BI}$  are relevant only when they are supplied by the external device (and not the memory controller).

<sup>4</sup> The maximum value of spec 8 for DATA[0:31] pins must be extended by 1.1 ns if the pins have been precharged to greater than  $V_{DDL}$ . This is the case if an external slave device on the bus is running at the max. value of VDATA<sub>PC</sub>. This is currently specified at 3.1 V. The 1.1 ns addition to spec 8 reflects the expected timing degradation for 3.1 V.

<sup>5</sup> The timing 27 refers to  $\overline{CS}$  when ACS = '00' and to  $\overline{WE}[0:3]/\overline{BE}[0:3]$  when CSNT = '0'.

### NOTE

The D[0:31] input timings 17 and 18 refer to the rising edge of the CLKOUT in which the  $\overline{TA}$  input signal is asserted.

| 14     | $\overline{\text{EVTI}}$ to $\overline{\text{RSTI}}$ Hold (at reset only)  | (4.0) x TC | —    | ns   |

**Figure F-30. Auxiliary Port Data Input Timing Diagram**

**Figure F-31. Auxiliary Port Data Output Timing Diagram**

MDO and  $\overline{\text{MSEO}}$  data is held valid until the next MCKO low transition.

When  $\overline{\text{RSTI}}$  is asserted,  $\overline{\text{EVTI}}$  is used to enable or disable the auxiliary port. Because MCKO probably is not active at this point, the timing must be based on the system clock. Since the system clock is not realized on the connector, its value must be known by the tool.

**Figure F-32. Enable Auxiliary From  $\overline{\text{RSTI}}$**

**Figure F-33. Disable Auxiliary From  $\overline{\text{RSTI}}$**

# F.12 RESET Timing

**Table F-14. RESET Timing**

**Note:** ( $V_{DD} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{DDH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ )

| 55  | $\overline{\text{SRESET}}$ negated to CLKOUT rising edge for DSDI and DSCK sample                              | $8 * TC$        | 200    |     | 142    |     | ns   |
| 55a | $\overline{\text{HRESET}}$ , $\overline{\text{SRESET}}$ , $\overline{\text{PORESET}}$ pulse width <sup>2</sup> |                 | 100    |     | 100    |     | ns   |

<sup>1</sup> Weak pull-ups and pull-downs used for Reset timing will comply with the 130  $\mu\text{A}$  mode select current outlined in <XrefBlue>Table F.5 on page F-7 The system requires two clocks of hold time on  $\overline{\text{RSTCONF}}/\overline{\text{TEXP}}$  after negation of  $\overline{\text{HRESET}}$ . The simplest way to insure meeting this requirement in systems that require the use of the  $\overline{\text{TEXP}}$  function, is to connect  $\overline{\text{RSTCONF}}/\overline{\text{TEXP}}$  to  $\overline{\text{SRESET}}$ .

<sup>2</sup>  $\overline{\text{HRESET}}$ ,  $\overline{\text{SRESET}}$  and  $\overline{\text{PORESET}}$  have a glitch detector to ensure that spikes less than 20 ns are rejected. The internal  $\overline{\text{HRESET}}$ ,  $\overline{\text{SRESET}}$  and  $\overline{\text{PORESET}}$  will assert only if these signals are asserted for more than 100 ns

<sup>1</sup> Conversion characteristics vary with  $F_{QCLK}$  rate. Reduced conversion accuracy occurs at max  $F_{QCLK}$  rate.

<sup>2</sup> The number of conversion cycles is dependent on the IST bit in the CCW register.

<sup>3</sup> At  $V_{RH} - V_{RL} = 5.12 \text{ V}$ , one count = 5 mV.

<sup>4</sup> Accuracy tested and guaranteed at  $V_{RH} - V_{RL} = 5.0 \text{ V} \pm 0.25 \text{ V}$

<sup>5</sup> This parameter is periodically sampled rather than 100% tested.

<sup>6</sup> Absolute error includes 1/2 count (~2.5 mV) of inherent quantization error and circuit (differential, integral, and offset) error. Specification assumes that adequate low-pass filtering is present on analog input pins — capacitive filter with 0.01  $\mu\text{F}$  to 0.1  $\mu\text{F}$  capacitor between analog input and analog ground, typical source isolation impedance of 10  $\text{K}\Omega$ .

<sup>7</sup> Input signals with large slew rates or high frequency noise components cannot be converted accurately. These signals may affect the conversion accuracy of other channels.

- <sup>8</sup> Accuracy tested and guaranteed at  $V_{ARH} - V_{RL} = 1.0V$  to  $0.75 \times V_{DDA}$  V. See Specification 52 in <XrefBlue>Table F-4 on page F-7.
- <sup>9</sup> This parameter is periodically sampled rather than 100% tested.
- <sup>10</sup> Absolute error includes 1/2 count (~2.5 mV) of inherent quantization error and circuit (differential, integral, and offset) error. Specification assumes that adequate low-pass filtering is present on analog input pins — capacitive filter with 0.01  $\mu F$  to 0.1  $\mu F$  capacitor between analog input and analog ground, typical source isolation impedance of 10 K $\Omega$ .
- <sup>11</sup> Input signals with large slew rates or high frequency noise components cannot be converted accurately. These signals may affect the conversion accuracy of other channels.
- <sup>12</sup> Below disruptive current conditions, the channel being stressed has conversion values of 0x3FF for analog inputs greater than  $V_{RH}$  and 0x000 for values less than  $V_{RL}$ . This assumes that  $V_{RH} \leq V_{DDA}$  and  $V_{RL} \geq V_{SSA}$  due to the presence of the sample amplifier. Other channels are not affected by non-disruptive conditions.
- <sup>13</sup> Exceeding limit may cause conversion error on stressed channels and on unstressed channels. Transitions within the limit do not affect device reliability or cause permanent damage.
- <sup>14</sup> Input must be current limited to the value specified. To determine the value of the required current-limiting resistor, calculate resistance values using  $V_{POSCLAMP} = (\text{the lower of } V_{DDA} \text{ or } V_{DDH}) + 0.3 \text{ V}$  and  $V_{NEGCLAMP} = -0.3 \text{ V}$ , then use the larger of the calculated values. The diode drop voltage is a function of current and varies approximately 0.4 to 0.8 V over temperature
- <sup>15</sup> This parameter is periodically sampled rather 100% tested.
- <sup>16</sup> Derate linearly to 0.3 mA if  $V_{DDH} - V_{DDA} = 1 \text{ V}$ . This specification is preliminary and may change after further characterization.
- <sup>17</sup> Condition applies to two adjacent pins.
- <sup>18</sup> Condition applies to all analog channels.
- <sup>19</sup> Note that -ve means current flows out of the pin.
- <sup>20</sup> Current Coupling Ratio, K, is defined as the ratio of the output current,  $I_{OUT}$ , measured on the pin under test to the injection current,  $I_{INJ}$ , when both adjacent pins are overstressed with the specified injection current.  $K = I_{OUT} / I_{INJ}$  The input voltage error on the channel under test is calculated as  $V_{err} = I_{INJ} \times K \times R_S$ .
- <sup>21</sup> Maximum source impedance is application-dependent. Error resulting from pin leakage depends on junction leakage into the pin and on leakage due to charge-sharing with internal capacitance. Error from junction leakage is a function of external source impedance and input leakage current. In the following expression, expected error in result value due to junction leakage is expressed in voltage ( $V_{ERRJ}$ ):  $V_{ERRJ} = R_S \times I_{OFF}$  where  $I_{OFF}$  is a function of operating temperature. Charge-sharing leakage is a function of input source impedance, conversion rate, change in voltage between successive conversions, and the size of the filtering capacitor used. Error levels are best determined empirically. In general, continuous conversion of the same channel may not be compatible with high source impedance
- <sup>22</sup> For a maximum sampling error of the input voltage  $\leq 1\text{LSB}$ , then the external filter capacitor,  $C_f \geq 1024 \times C_{SAMP}$  The value of  $C_{SAMP}$  in the new design may be reduced.

|      | Output (PDMCR[SLRC0] = 0), 50 pF Load <sup>1</sup>                                                                            | $t_{FO}$ | -   | 50  | ns      |
|      | Output (PDMCR[SLRC0] = 1), 50 pF Load                                                                                         | $t_{FO}$ | -   | 21  | ns      |

**Table F-19. GPIO Timing (continued)**

**Note:** ( $T_A = T_L$  to  $T_H$ )

|      |                                       |          |   |    |         |
|------|---------------------------------------|----------|---|----|---------|
| 123c | SGPIOC[0, 5] fall time. <sup>2</sup>  |          |   |    |         |
|      | Input                                 | $t_{FI}$ | - | 1  | $\mu s$ |
|      | Output (SCCR[COM] = 0b11), 25 pF Load | $t_{FO}$ | - | 10 | ns      |
|      | Output (SCCR[COM] = 0b00), 50 pF Load | $t_{FO}$ | - | 10 | ns      |

<sup>1</sup> For this 5-V output, a drive load of 200 pF is possible but with a rise/fall time of 300 ns.

<sup>2</sup> These are 2.6 V GPIO pins.

## F.17 TPU3 Electrical Characteristics

**Table F-20. TPU3 Timing**

**Note:** ( $T_A = T_L$  to  $T_H$ )

| Num | Rating                                                                                                                                 | Symbol      | Min | Max | Unit      |
|-----|----------------------------------------------------------------------------------------------------------------------------------------|-------------|-----|-----|-----------|
| 124 | Slew Rate of TPU Output Channel Valid <sup>1,2</sup><br>(SLRC0 of PDMCR = 0, 50 pF to 200 pF load)<br>(SLRC0 of PDMCR = 1, 50 pF load) | $t_{CHTOV}$ | 92  | 650 | ns        |
|     |                                                                                                                                        |             | 3   | 25  | ns        |
| 125 | CLKOUT High to TPU Output Channel Hold                                                                                                 | $t_{CHTOH}$ | 0   | 15  | ns        |
| 126 | TPU Input Channel Pulse Width <sup>3</sup>                                                                                             | $t_{TIPW}$  | 4   | —   | $t_{cyc}$ |

<sup>1</sup> AC timing is shown with respect to 10%  $V_{DD}$  & 90%  $V_{DD}$  levels.

<sup>2</sup> Timing not valid for external T2CLK input.

<sup>3</sup>  $t_{cyc}$  is defined as the CLKOUT Period.

**Figure F-44. TPU3 Timing**

## F.18 TouCAN Electrical Characteristics

| 134     | Sequential Transfer Delay             | $t_{TD}$  | $9 \cdot tcyc$                    | $17 \cdot tcyc$  | ns   |
| 135     | Data Setup Time (Inputs)              | $t_{SU}$  | 30                                | —                | ns   |
| 136     | Data Hold Time (Inputs)               | $t_{HI}$  | 0                                 | —                | ns   |
| 137     | Data Valid (After PPM_TCLK Edge)      | $t_V$     | —                                 | 5                | ns   |
| 138     | Data Hold Time (Outputs)              | $t_{HO}$  | $TC/2$                            | —                | ns   |

**Table F-22. PPM Timing (continued)**

**Note:** ( $T_A = T_L$  to  $T_H$ , 50 pF Load on all Pins)

| Nu<br>m | Rating                                                                         | Symbol   | Min    | Max     | Unit     |
|---------|--------------------------------------------------------------------------------|----------|--------|---------|----------|
| 139     | Rise Time                                                                      | $t_{HI}$ | —      | 1       | $\mu s$  |
|         | Input                                                                          |          |        |         |          |
|         | Output –<br>2.6V PPM pads (PDMCR2[PPMV] = 0)<br>5V PPM pads (PDMCR2[PPMV] = 1) | $t_{RO}$ | —<br>— | 7<br>15 | ns<br>ns |
| 140     | Fall Time                                                                      | $t_{FI}$ | —      | 1       | $\mu s$  |
|         | Input                                                                          |          |        |         |          |
|         | Output –<br>2.6V PPM pads (PDMCR2[PPMV] = 0)<br>5V PPM pads (PDMCR2[PPMV] = 1) | $t_{FO}$ | —<br>— | 7<br>15 | ns<br>ns |

<sup>1</sup> All AC timing is tested to the 2.6-V levels outlined in <XrefBlue>Table F.5 on page F-7.

<sup>2</sup> Although the PPM permits frequencies of up to  $f_{SYS}/2$ , if the 5-V bus is selected the bus frequency should not be run at frequencies above  $f_{SYS}/8$  for EMI/EMC reasons.

<sup>3</sup> TC is defined to be the clock period.

Following are PPM timing diagrams.

**Figure F-45. PPM\_TCLK Timing**

**Figure F-46. PPM Data Transfer Timing (SPI Mode)**

## F.20 MIOS Timing Characteristics

All MIOS output pins are slew rate controlled. Slew rate control circuitry adds 90 ns as minimum to the output timing and 650 ns as a maximum. This slew rate is from 10%  $V_{DD}$  to 90%  $V_{DD}$ , an additional 100 ns should be added for total 0 to  $V_{DD}$  slew rate.

**Table F-23. MCPSM Timing Characteristics**

**Note:** After reset MCPSMSCR\_PSL[3:0] is set to 0b0000.

**Note:** VS\_PCLK is the MIOS prescaler clock which is distributed to all the counter (e.g., MPWMSM and MMCSM) submodules.

| Characteristic                             | Symbol      | Delay                   | Unit                |
|--------------------------------------------|-------------|-------------------------|---------------------|
| MCPSM enable to VS_PCLK pulse <sup>1</sup> | $t_{CPSMC}$ | (MCPSMSCR_PSL[3:0]) - 1 | System Clock Cycles |

<sup>1</sup> The MCPSM clock prescaler value (MCPSMSCR\_PSL[3:0]) should be written to the MCPSMSCR (MCPSM Status/Control Register) before rewriting the MCPSMSCR to set the enable bit (MCPSMSCR\_PREN). If this is not done the prescaler will start with the old value in the MCPSMSCR\_PSL[3:0] before reloading the new value into the counter.

Note 1:  $f_{SYS}$  is the internal system clock for the IMB3 bus.

Note 2: The numbers associated with the  $f_{SYS}$  ticks refer to the IMB3 internal state.

Note 3: vs\_pclk is the MIOS prescaler clock which is distributed around the MIOS to counter modules such as the MMCSM and MPWMSM.

**Figure F-47. MCPSM Enable to VS\_PCLK Pulse Timing Diagram**

### F.20.1 MPWMSM Timing Characteristics

**Table F-24. MPWMSM Timing Characteristics**

**Note:** All delays are in system clock periods.

| Characteristic                | Symbol     | Min            | Max              |
|-------------------------------|------------|----------------|------------------|
| PWMSM output resolution       | $t_{PWMR}$ | — <sup>1</sup> | 2.0 <sup>2</sup> |
| PWM output pulse <sup>3</sup> | $t_{PWMO}$ | 2.0            | —                |

**Table F-24. MPWMSM Timing Characteristics (continued)**

**Note:** All delays are in system clock periods.

| Characteristic                                                 | Symbol     | Min                                                                                                       | Max |
|----------------------------------------------------------------|------------|-----------------------------------------------------------------------------------------------------------|-----|
| MPWMI input pin to MPWMSCR_PIN status set                      | $t_{PIN}$  | 1                                                                                                         | 2   |
| CPSM enable to output set <sup>4</sup>                         | $t_{PWMP}$ | $(MPWMPERR - MPWMPULR + 1) * (256 - MPWMSCR\_CP) * MCPSMSCR\_PSL + 1$                                     |     |
| MPWMSM Enable to output set (MIN) <sup>5</sup>                 | $t_{PWME}$ | $(MPWMPERR - MPWMPULR) * (256 - MPWMSCR\_CP) * MCPSMSCR\_PSL + 3 + (255 - MPWMSCR\_CP) * MCPSMSCR\_PSL^6$ |     |
| MPWMSM Enable to output set (MAX) <sup>5</sup>                 | $t_{PWME}$ | $t_{PWME(MIN)} + MCPSMSCR\_PSL - 1^6$                                                                     |     |
| Interrupt Flag to output pin reset (period start) <sup>7</sup> | $t_{FLGP}$ | $(256 - MPWMSCR\_CP) * MCPSMSCR\_PSL - 1^6$                                                               |     |

<sup>1</sup> Minimum output resolution depends on MPWMSM and MCPSM prescaler settings.

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSL[3:0] = 0x2 and MPWMSCR\_CP[7:0] = 0xFF.

<sup>3</sup> Excluding the case where the output is always "0".

<sup>4</sup> With MPWMSM enabled before enabling the MCPSM. Please also see NOTE 1 on the MCPSM timing information.

<sup>5</sup> The exact timing from MPWMSM enable to the pin being set depends on the timing of the register write and the MCPSM VS\_PCLK.

<sup>6</sup> When MCPSMSCR\_PSL = 0x0000, this gives a prescale value of 16 and it is 16 which should be used in these calculations. When MCPSMSCR\_PSL = 0x0001, the CPSM is inactive.

<sup>7</sup> The interrupt is set before the output pin is reset (Signifying the start of a new period).

## F.20.2 MMCSM Timing Characteristics

**Table F-25. MMCSM Timing Characteristics**

**Note:** All delays are in system clock periods.

| Characteristic                                           | Symbol      | Min                                                                                     | Max            |
|----------------------------------------------------------|-------------|-----------------------------------------------------------------------------------------|----------------|
| MMCSM input pin period                                   | $t_{PPER}$  | 4                                                                                       | —              |
| MMCSM pin low time                                       | $t_{PLO}$   | 2                                                                                       | —              |
| MMCSM pin high time                                      | $t_{PHI}$   | 2                                                                                       | —              |
| clock pin to counter bus increment.                      | $t_{PCCB}$  | 1                                                                                       | 2              |
| load pin to new counter bus value                        | $t_{PLCB}$  | 1                                                                                       | 2              |
| clock pin to PINC delay                                  | $t_{PINC}$  | 1                                                                                       | 2              |
| Load pin to PINL delay                                   | $t_{PINL}$  | 1                                                                                       | 2              |
| Counter bus resolution                                   | $t_{CBR}$   | — <sup>1</sup>                                                                          | 2 <sup>2</sup> |
| Counter bus overflow reload to interrupt flag            | $t_{CBFLG}$ | 1                                                                                       |                |
| MCPSM enable to counter bus increment.                   | $t_{MCMP}$  | $(256 - \text{MMCSMSCR\_CP}) * \text{MCPSMSCR\_PSL} + 2$                                |                |
| MMCSM Enable to counter bus increment (MIN) <sup>3</sup> | $t_{MCME}$  | $4 + \text{MCPSMSCR\_PSL} * (255 - \text{MMCSMSCR\_CP})^3$                              |                |
| MMCSM Enable to counter bus increment (MAX) <sup>3</sup> | $t_{MCME}$  | $4 + \text{MCPSMSCR\_PSL} * (255 - \text{MMCSMSCR\_CP}) + (\text{MCPSMSCR\_PSL} - 1)^3$ |                |

<sup>1</sup> Minimum output resolution depends on MMCSM and MCPSM prescaler settings.

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSEL[3:0] = 0x2 and MMCSMSCR\_CP[7:0] = 0xFF.

<sup>3</sup> The exact timing from MMCSM enable to the pin being set depends on the timing of the MMCSMSCR register write and the MCPSM VS\_PCLK. The MMCSM enable is taken to mean the MMCSMSCR\_CLS[1:0] being written to 2'b11.

**Figure F-52. MMCSM Minimum Input Pin (Either Load Or Clock) Timing Diagram**

## F.20.3 MDASM Timing Characteristics

Table F-26. MDASM Timing Characteristics

**Note:** All delays are in system clock periods.

| Characteristics                          | Symbol      | Min | Max            |
|------------------------------------------|-------------|-----|----------------|
| <b>Input Modes: (IPWM, IPM, IC, DIS)</b> |             |     |                |
| MDASM input pin period                   | $t_{PPER}$  | 4   | —              |
| MDASM pin low time                       | $t_{PLO}$   | 2   | —              |
| MDASM pin high time                      | $t_{PHI}$   | 2   | —              |
| Input capture resolution                 | $t_{CAPR}$  | —   | 2              |
| Input pin to Counter Bus capture delay   | $t_{PCAP}$  | 1   | 3 <sup>1</sup> |
| Input pin to interrupt flag delay        | $t_{PFLG}$  | 2   | 3              |
| Input pin to PIN delay                   | $t_{PIN}$   | 1   | 2              |
| Counter bus resolution                   | $t_{CBR}$   | —   | 2 <sup>2</sup> |
| <b>Output Modes: (OC, OPWM)</b>          |             |     |                |
| Output pulse width <sup>3</sup>          | $t_{PULW}$  | 2   | —              |
| Compare resolution <sup>3</sup>          | $t_{COMR}$  | —   | 2 <sup>2</sup> |
| Counter Bus to pin change                | $t_{CBP}$   | 3   |                |
| Counter Bus to interrupt flag set.       | $t_{CBFLG}$ | 3   |                |

<sup>1</sup> If the counter bus capture occurs when the counter bus is changing then the capture is delayed one cycle. In situations where the counter bus is stable when the input capture occurs the  $t_{PCAP}$  has a maximum delay of two cycles (the one-cycle uncertainty is due to the synchronizer).

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSL[3:0] = 0x2 and MDASMSR\_CP[7:0] = 0xFF.

<sup>3</sup> Maximum output resolution and pulse width depends on counter (e.g., MMCSM) and MCPSM prescaler settings.

## F.21 MPIO SM Timing Characteristics

Table F-27. MPIO SM Timing Characteristics

**Note:** All delays are in system clock periods.

| Characteristic           | Symbol     | Min            | Max |
|--------------------------|------------|----------------|-----|
| <b>Input Mode</b>        |            |                |     |
| MPIO SM input pin period | $t_{PPER}$ | — <sup>1</sup> | —   |

**Table F-27. MPIO SM Timing Characteristics**

**Note:** All delays are in system clock periods.

| Characteristic                  | Symbol     | Min            | Max |
|---------------------------------|------------|----------------|-----|
| MPIO SM pin low time            | $t_{PLO}$  | — <sup>1</sup> | —   |
| MPIO SM pin high time           | $t_{PHI}$  | — <sup>1</sup> | —   |
| Input pin to MPIO SM_DR delay   | $t_{PDR}$  | 0              | 1   |
| <b>Output mode</b>              |            |                |     |
| Output pulse width <sup>2</sup> | $t_{PULW}$ | — <sup>2</sup> | —   |

<sup>1</sup> The minimum input pin period, pin low and pin high times depend on the rate at which the MPIO SM\_DR register is polled.

<sup>2</sup> The minimum output pulse width depends on how quickly the CPU updates the value inside the MPIO SM\_DR register.

**Figure F-63. MPIO SM Input Pin to MPIO SM\_DR (Data Register) Timing Diagram**

**NOTE**

$f_{SYS}$  is the internal system clock for the IMB3 bus.

## F.22 Pin Summary

Table F-28. MPC561/MPC563 Signal Names and Pin Names

| Signal Name       | Pin Name      | Ball Assignment |
|-------------------|---------------|-----------------|
| USIU              |               |                 |
| ADDR/SGPIOA[8:31] | addr_sgpioa8  | AF9             |
|                   | addr_sgpioa9  | AF8             |
|                   | addr_sgpioa10 | AC6             |
|                   | addr_sgpioa11 | Y4              |
|                   | addr_sgpioa12 | Y3              |
|                   | addr_sgpioa13 | AD7             |
|                   | addr_sgpioa14 | AE7             |
|                   | addr_sgpioa15 | AF7             |
|                   | addr_sgpioa16 | AD8             |
|                   | addr_sgpioa17 | AE8             |
|                   | addr_sgpioa18 | AC7             |
|                   | addr_sgpioa19 | AD9             |

<sup>1</sup> This pin also included the MDO5 function on the K27S mask set off the MPC561.

<sup>2</sup> MPC563 only, no connection on MPC561.

### F.22.1 Package Diagrams

The package for the MPC561/MPC563 is the 388 PBGA (27 x 27 mm, 1.0 mm ball pitch). This package has 352 balls in the perimeter rows and 36 ground balls in the center island for a total of 388 balls. The case outline drawing is 1164-01, as shown in [Figure F-64](#).

NOTES

1. DIMENSIONS AND TOLERANCING PER ASME Y14.5M-1994.

2. DIMENSIONS IN MILLIMETERS.

3. DIMENSION IS MEASURED AT THE MAXIMUM SOLDER BALL DIAMETER, PARALLEL TO PRIMARY DATUM A.

4. PRIMARY DATUM A AND THE SEATING PLANE ARE DEFINED BY THE SPHERICAL CROWNS OF THE SOLDER BALLS.

| DIM       | MILLIMETERS |                                | INCHES |     | DIM | MILLIMETERS |     | INCHES       |     |

### F.22.1.1 MPC561/MPC563 Ball Map

The ball diagram of the MPC561/MPC563 is shown in [Figure F-66](#).

**NOTE:** The Flash balls are only available on the MPC563 and MPC564. These are no connects on the MPC561 and MPC562. Flash supplies and inputs are located on the following balls: T23, T24, U24, U25, U26.

## Appendix G

### 66-MHz Electrical Characteristics

This appendix contains detailed information on power considerations, DC/AC electrical characteristics, and AC timing characteristics of the MPC561/MPC563 at the optional operating frequency of 66 MHz. For information on the 40- and 56-MHz operating frequency, refer to [Appendix F, “Electrical Characteristics.”](#)

#### G.1 66-MHz Feature Limitations

The following feature limitations apply when operating the MPC561/MPC563 at a system frequency of 66 MHz:

- Internal Flash programming must be performed with a system frequency of 56 MHz or less.
- Data Bus Pre-discharge cannot be used to prevent damage due to voltages higher than 3.1 V on the data bus.
- In a dual controller application with the MPC563 as master and MPC561 as slave, revision D of MPC561 silicon must be used.

**Table G-1. Absolute Maximum Ratings (VSS = 0V)**

|    | Rating                                                        | Symbol                             | Min. Value           | Max. Value       | Unit |
|----|---------------------------------------------------------------|------------------------------------|----------------------|------------------|------|
| 1  | 2.6-V Supply Voltage <sup>1</sup>                             | V <sub>DDL</sub>                   | -0.3                 | 3.0 <sup>2</sup> | V    |

| 19a | Operating Temperature Range – Ambient (Packaged), C temperature range.                       | T <sub>A</sub>   | -40 (T <sub>L</sub> ) | +85 (T <sub>H</sub> )  | °C   |
| 20  | Operating Temperature Range – Solder Ball (Packaged any perimeter solder ball) <sup>14</sup> | T <sub>SB</sub>  | -40 (T <sub>L</sub> ) | +135 (T <sub>H</sub> ) | °C   |
| 21  | Junction Temperature Range                                                                   | T <sub>J</sub>   | -40                   | +150                   | °C   |
| 22  | Storage Temperature Range                                                                    | T <sub>STG</sub> | -55                   | +150                   | °C   |
| 23  | Maximum Solder Temperature <sup>15</sup>                                                     | T <sub>SDR</sub> | —                     | 235                    | °C   |
| 24  | Moisture Sensitivity Level <sup>16</sup>                                                     | MSL              | —                     | 3                      | —    |

<sup>1</sup> For internal digital supply of V<sub>DDL</sub> = 2.6-V typical.

<sup>2</sup> 2.6 volt supply pins can withstand up to 3.6 volts for accumulative time of 24 hours over the lifetime of the device.

<sup>3</sup> During operation the value of V<sub>FLASH</sub> must be 5.0 V ±5%

<sup>4</sup> These power supplies are available on MPC563 and MPC564 only.

<sup>5</sup> Maximum average current into the IRAMSTBY pin must be < 1.75mA.

<sup>6</sup> V<sub>DDA</sub>=5.0 V ±5%.

<sup>7</sup> All 2.6-V input-only pins are 5-V tolerant.

<sup>8</sup> Note that long term reliability may be compromised if 2.6-V output drivers drive a node which has been previously pulled to >3.1 V by an external component. HRESET and SRESET are fully 5-V compatible.

<sup>9</sup> 6.35 V on 5-V only pins (all QADC, all TPU, all QSMCM and the following MIOS pins: MDA[11:15], MDA[27:31], MPWM16, MPIO32B[7:9]/MPWM[20:21], MPIO32B11/C\_CNRX0, MPIO32B12/C\_CNTX0). Internal structures hold the input voltage below this maximum voltage on all of these pins, except the QSMCM RXD1/QPI1 and RXD2/QPI2/C\_CNRX0 pins, if the maximum injection current specification is met (1 mA for all pins; exception: 3 mA on QADC pins) and VDDH is within Operating Voltage specifications (see specification 43 in [Table G-4](#)). Exception: The RXD1/QGPI1 and RXD2/GPI2 pins do not have clamp diodes to VDDH. Voltage must be limited to less than 6.5 volts on these 2 pins to prevent damage.

<sup>10</sup> Maximum continuous current on I/O pins provided the overall power dissipation is below the power dissipation of the package. Proper operation is not guaranteed at this condition.

<sup>11</sup> Condition applies to one pin at a time.

<sup>12</sup> Transitions within the limit do not affect device reliability or cause permanent damage. Exceeding limit may cause permanent conversion error on stressed channels and on unstressed channels.

<sup>13</sup> Maximum transient current per ISO7637.

<sup>14</sup> Maximum operating temperature on any solder ball in outer four rows of solder balls on the package. These rows are referred to as “Perimeter Balls” to distinguish them from the balls in the center of the package.

<sup>15</sup> Solder profile per CDF-AEC-Q100, current revision.

<sup>16</sup> Moisture sensitivity per JEDEC test method J-STD-020-A (April 1999).

Functional operating conditions are given in [Section G.6, “DC Electrical Characteristics.”](#) Absolute maximum ratings are stress ratings only, and functional operation at the maximum is not guaranteed. Stress beyond those listed may affect device reliability or cause permanent damage to the device.

This device contains circuitry protecting against damage due to high static voltage or electrical fields; however, it is advised that normal precautions be taken to avoid application of any voltages higher than maximum-rated voltages to this high-impedance circuit. Reliability of operation is enhanced if unused inputs are tied to an appropriate logic voltage level (e.g., either  $V_{SS}$  or  $V_{DD}$ ).

### NOTE

Negative current flows out of the pin and positive current flows into the pin.

## G.2 Package

The MPC561/MPC563 is available in packaged form. The package is a 388-ball PBGA having a 1.0 mm ball pitch, Freescale case outline 1164-01 (See [Figure G-63](#) and [Figure G-64](#)).

## G.3 EMI Characteristics

### G.3.1 Reference Documents

The document referenced for the EMC testing of MPC561/MPC563 is SAE J1752/3 Issued 1995-03

### G.3.2 Definitions and Acronyms

EMC – Electromagnetic Compatibility

EMI – Electromagnetic Interference

TEM cell – Transverse Electromagnetic Mode cell

### G.3.3 EMI Testing Specifications

1. Scan range: 150 KHz – 1000 MHz
2. Operating Frequency: 66 MHz
3. Operating Voltages: 2.6 V, 5.0 V
4. Max spikes: TBD dBuV
5. I/O port waveforms: Per J1752/3
6. Temperature: 25 °C

## G.4 Thermal Characteristics

Table G-2. Thermal Characteristics

| Characteristic                                                                                          | Symbol           | Value                 | Unit |
|---------------------------------------------------------------------------------------------------------|------------------|-----------------------|------|
| BGA Package Thermal Resistance,<br>Junction to Ambient – Natural Convection                             | $R_{\theta JA}$  | 47.3 <sup>1,2,3</sup> | °C/W |
| BGA Package Thermal Resistance,<br>Junction to Ambient – Four layer (2s2p) board, natural<br>convection | $R_{\theta JMA}$ | 29.4 <sup>3,4,5</sup> | °C/W |

**Table G-2. Thermal Characteristics (continued)**

| Characteristic                                                              | Symbol          | Value               | Unit |
|-----------------------------------------------------------------------------|-----------------|---------------------|------|
| BGA Package Thermal Resistance, Junction to Board                           | $R_{\theta JB}$ | 21.2 <sup>3,6</sup> | °C/W |
| BGA Package Thermal Resistance, Junction to Case (top)                      | $R_{\theta JT}$ | 7.0 <sup>3,7</sup>  | °C/W |
| BGA Package Thermal Resistance, Junction to Package Top, Natural Convection | $\Psi_{JT}$     | 1.6 <sup>8</sup>    | °C/W |

<sup>1</sup> Junction temperature is a function of on-chip power dissipation, package thermal resistance, mounting site (board) temperature, ambient temperature, air flow, power dissipation of other components on the board, and the board thermal resistance.

<sup>2</sup> Per SEMI G38-87 and JESD51-2 with the board horizontal.

<sup>3</sup> These values are the mean + 3 standard deviations of characterized data.

<sup>4</sup> Junction temperature is a function of on-chip power dissipation, package thermal resistance, mounting site (board) temperature, ambient temperature, air flow, power dissipation of other components on the board, and the board thermal resistance.

<sup>5</sup> Per JESD51-6 with the board horizontal.

<sup>6</sup> Thermal resistance between the die and the printed circuit board (Four layer (2s2p) board, natural convection).

<sup>7</sup> Indicates the thermal resistance between the die and the case top surface as measured by the cold plate method (MIL SPEC-883 Method 1012.1) with the cold plate temperature used for the case temperature.

<sup>8</sup> Thermal characterization parameter indicating the temperature difference between package top and the junction temperature per EIA/JESD51-2.

An estimation of the chip junction temperature,  $T_J$ , in °C can be obtained from the equation:

$$T_J = T_A + (R_{\theta JA} \times P_D)$$

where:

$T_A$  = ambient temperature (°C)

$R_{\theta JA}$  = package junction to ambient resistance (°C/W)

$P_D$  = power dissipation in package

The junction to ambient thermal resistance is an industry standard value which provides a quick and easy estimation of thermal performance. Unfortunately, the answer is only an estimate; test cases have demonstrated that errors of a factor of two are possible. As a result, more detailed thermal characterization is supplied.

Historically, the thermal resistance has frequently been expressed as the sum of a junction to case thermal resistance and a case to ambient thermal resistance:

$$R_{\theta JA} = R_{\theta JC} + R_{\theta CA}$$

where:

$R_{\theta JA}$  = junction to ambient thermal resistance (°C/W)

$R_{\theta JC}$  = junction to case thermal resistance (°C/W)

$R_{\theta CA}$  = case to ambient thermal resistance (°C/W)

$R_{\theta JC}$  is device related and cannot be influenced. The user controls the thermal environment to change the case to ambient thermal resistance,  $R_{\theta CA}$ . For instance, the air flow can be changed around the device, add a heat sink, change the mounting arrangement on printed circuit board, or change the thermal dissipation on the printed circuit board surrounding the device. This description is most useful for ceramic packages with heat sinks where about 90% of the heat flow is through the case to the heat sink to ambient. For most packages, a better model is required.

The simplest thermal model of a package which has demonstrated reasonable accuracy (about 20 percent) is a two resistor model consisting of a junction to board and a junction to case thermal resistance. The junction to case covers the situation where a heat sink will be used or where a substantial amount of heat is dissipated from the top of the package. The junction to board thermal resistance describes the thermal performance when most of the heat is conducted to the printed circuit board. It has been observed that the thermal performance of most plastic packages and especially PBGA packages is strongly dependent on the board temperature.

If the board temperature is known, an estimate of the junction temperature in the environment can be made using the following equation:

$$T_J = T_B + (R_{\theta JB} \times P_D)$$

where:

$T_B$  = board temperature ( $^{\circ}\text{C}$ )

$R_{\theta JB}$  = package junction to board resistance ( $^{\circ}\text{C}/\text{W}$ )

$P_D$  = power dissipation in package ( $\Omega$ )

If the board temperature is known and the heat loss from the package case to the air can be ignored, acceptable predictions of junction temperature can be made. For this method to work, the board and board mounting must be similar to the test board used to determine the junction to board thermal resistance, namely a 2s2p (board with a power and a ground plane) and vias attaching the thermal balls to the ground plane.

When the board temperature is not known, a thermal simulation of the application is needed. The simple two-resistor model can be used with the thermal simulation of the application (2), or a more accurate and complex model of the package can be used in the thermal simulation. Consultation on the creation of the complex model is available.

To determine the junction temperature of the device in the application after prototypes are available, the thermal characterization parameter ( $\Psi_{JT}$ ) can be used to determine the junction temperature with a measurement of the temperature at the top center of the package case using the following equation:

$$T_J = T_T + (\Psi_{JT} \times P_D)$$

where:

$T_T$  = thermocouple temperature on top of package ( $^{\circ}\text{C}$ )

$\Psi_{JT}$  = thermal characterization parameter

$P_D$  = power dissipation in package

The thermal characterization parameter is measured per JESD51-2 specification published by JEDEC using a 40 gauge type-T thermocouple epoxied to the top center of the package case. The thermocouple

should be positioned so that the thermocouple junction rests on the package. A small amount of epoxy is placed over the thermocouple junction and over about one mm of wire extending from the junction. The thermocouple wire is placed flat against the package case to avoid measurement errors caused by cooling effects of the thermocouple wire.

## G.5 ESD Protection

**Table G-3. ESD Protection**

| Characteristics                             | Symbol | Value | Units    |
|---------------------------------------------|--------|-------|----------|
| ESD for Human Body Model (HBM) <sup>1</sup> |        | 2000  | V        |
| HBM Circuit Description                     | R1     | 1500  | $\Omega$ |
|                                             | C      | 100   | pF       |
| ESD for Machine Model (MM)                  |        | 200   | V        |
| MM Circuit Description                      | R1     | 0     | $\Omega$ |
|                                             | C      | 200   | pF       |
| Number of pulses per pin <sup>2</sup>       |        |       | —        |
| Positive pulses (MM)                        | —      | 3     |          |
| Negative pulses (MM)                        | —      | 3     |          |
| Positive pulses (HBM)                       | —      | 1     |          |
| Negative pulses (HBM)                       | —      | 1     |          |
| Interval of Pulses                          | —      | 1     | S        |

<sup>1</sup> All ESD testing is in conformity with CDF-AEC-Q100 Stress Test Qualification for Automotive Grade Integrated Circuits.

<sup>2</sup> A device will be defined as a failure if after exposure to ESD pulses the device no longer meets the device specification requirements. Complete DC parametric and functional testing shall be performed per applicable device specification at room temperature followed by hot temperature, unless specified otherwise in the device specification.

## G.6 DC Electrical Characteristics

**Note:** ( $V_{DD} = 2.6\text{ V} \pm 0.1\text{ V}$ ,  $V_{DDH} = 5.0\text{ V} \pm 0.25\text{ V}$ ,  $T_A = T_L$  to  $T_H$ )

**Table G-4. DC Electrical Characteristics**

<sup>1</sup> This characteristic is for 2.6-V output and 5-V input friendly pins.

## 66-MHz Electrical Characteristics

- <sup>2</sup> This characteristic is for 5-V output and 5-V input pins.
- <sup>3</sup>  $0.3V > V_{DDA}$  or  $V_{DDH}$ , whichever is greater.
- <sup>4</sup> Within this range, no significant injection will be seen. See QADC64 Disruptive Input Current ( $I_{NA}$ ).
- <sup>5</sup> During reset all 2.6V and 2.6V/5V pads will leak up to  $10\mu A$  to QVDDL if the pad has a voltage  $> QVDDL$ .
- <sup>6</sup> Maximum leakage occurs at maximum operating temperature. Current decreases by approximately one-half for each 8 to 12 °C, in the ambient temperature range of 50 to 125 °C.
- <sup>7</sup> All bus pins support two drive strengths capabilities, 25 pF and 50 pF. Current drive is less at the 25-pF capacitive load. Both modes achieve 66-MHz timing.
- <sup>8</sup> Only IRQ, TPU, MIOS, GPIO, QADC (when digital inputs) and RESET pins have hysteresis, thus there is no hysteresis specification on all other pins
- <sup>9</sup> Transient currents can reach 50mA.
- <sup>10</sup> KAPWR and IRAMSTBY can be powered-up prior to any other supply or at the same time as the other 2.6 V supplies. IRAMSTBY must lead or coincide with VDD; however it can lag KAPWR.
- <sup>11</sup> This parameter is periodically sampled rather than 100% tested
- <sup>12</sup> Up to 0.5 V during power up/down.
- <sup>13</sup> To obtain full-range results,  $V_{SSA} \leq V_{RL} \leq V_{INDC} \leq V_{RH} \leq V_{DDA}$
- <sup>14</sup> When using the QADC in legacy mode it is recommended to connect this pin to 2.6V or 3.3V, however it can be connected to 0V or 5V without damage to the device.
- <sup>15</sup> A resistor must be placed in series with the IRAMSTBY power supply. Refer to [Appendix C, "Clock and Board Guidelines."](#)
- <sup>16</sup> All injection current is transferred to the  $V_{DDH}$ . An external load is required to dissipate this current to maintain the power supply within the specified voltage range.
- <sup>17</sup> Absolute maximum voltage ratings for each pin (see [Table G-1](#)) must also be met during this condition.
- <sup>18</sup> Total injection current for all I/O pins on the chip must not exceed 20 mA (sustained current). Exceeding this limit can cause disruption of normal operation.
- <sup>19</sup> Current refers to two QADC64 modules operating simultaneously.
- <sup>20</sup> Below disruptive current conditions, the channel being stressed has conversion values of 0x3FF for analog inputs greater than  $V_{RH}$  and 0x000 for values less than  $V_{RL}$ . This assumes that  $V_{RH} \leq V_{DDA}$  and  $V_{RL} \geq V_{SSA}$  due to the presence of the sample amplifier. Other channels are not affected by non-disruptive conditions.

## G.7 Oscillator and PLL Electrical Characteristics

**Note:** ( $V_{DD} = 2.6 V \pm 0.1 V$ ,  $V_{DDH} = 5.0 V \pm 0.25 V$ ,  $T_A = T_L$  to  $T_H$ )

**Table G-5. Oscillator and PLL**

|   | Characteristic                                                                                   | Symbol                   | Min            | Typical | Max               | Unit            |

**Table G-5. Oscillator and PLL (continued)**

|   | Characteristic           | Symbol    | Min | Typical | Max | Unit |
|---|--------------------------|-----------|-----|---------|-----|------|
| 8 | Oscillator Drive (XTAL)  | $I_{OSC}$ | 7   |         | —   | mA   |
| 9 | Oscillator Bias Resistor | $R_{OSC}$ | 0.5 | 1       | 3   | MΩ   |

<sup>1</sup> Assumes stable power and oscillator.

<sup>2</sup>  $F_{VCOOUT}$  is 2x the system frequency.

<sup>3</sup> Estimated value, real values to be characterized and updated.

## G.8 Flash Electrical Characteristics

The characteristics found in this section apply only to the MPC563.

### NOTE

Flash programming should be restricted to 56 MHz.

Flash read operations are unaffected by this condition.

**Note:** ( $V_{DDF} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{FLASH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ ,  $T_B = T_L$  to  $T_H$ )

**Table G-6. Array Program and Erase Characteristics**

| Symbol       | Meaning                              | Value   |                      |         | Units |
|--------------|--------------------------------------|---------|----------------------|---------|-------|
|              |                                      | Minimum | Typical <sup>1</sup> | Maximum |       |
| $T_{ERASE}$  | Block Erase Time <sup>2</sup>        |         | 3                    | 12      | s     |
| $T_{ERASEM}$ | Module Erase Time <sup>2</sup>       |         | 13                   | 60      | s     |
| $T_{PROG}$   | Word Programming Time <sup>3,4</sup> |         | 15                   | 20      | μs    |

<sup>1</sup> Typical program and erase times assume nominal supply values and 25 °C.

<sup>2</sup> Erase time specification does not include pre-programming operation

<sup>3</sup> Word size is 32 bits.

<sup>4</sup> The maximum hardware programming time of the entire Flash (not including the shadow row) is 20 μs x (512 Kbytes / 4 bytes per word), or 131,072 words, (no software overhead).

**Note:** ( $V_{DDF} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{FLASH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ ,  $T_B = T_L$  to  $T_H$ )

**Table G-7. CENSOR Cell Program and Erase Characteristics**

| Symbol      | Meaning                            | Value   |                      |         | Units |
|-------------|------------------------------------|---------|----------------------|---------|-------|
|             |                                    | Minimum | Typical <sup>1</sup> | Maximum |       |
| $T_{CLEAR}$ | CENSOR Bit Clear Time <sup>2</sup> |         | 13                   | 60      | s     |
| $T_{SET}$   | CENSOR Bit Set Time                |         | 115                  | 250     | μs    |

<sup>1</sup> Typical set and clear times assume nominal supply values and 25 °C.

<sup>2</sup> Clear time specification does not include pre-set operation.

**Table G-8. Flash Module Life**

| Symbol                               | Meaning                                                                                                                                     | Value                                                  |
|--------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------|
| Array P/E Cycles <sup>1</sup>        | Maximum number of Program/Erase cycles per block to guarantee data retention.                                                               | 1,000                                                  |
| CENSOR Set/Clear Cycles <sup>2</sup> | Minimum number of Program/Erase cycles per bit before failure.                                                                              | 100                                                    |
| Array and CENSOR Data Retention      | Minimum data retention at an average of 85 °C junction temperature.<br>Minimum data retention at an average of 125 °C junction temperature. | Min 15 years <sup>3</sup><br>Min 10 years <sup>3</sup> |

<sup>1</sup> A Program/Erase cycle is defined as switching the bits from 1 to 0 to 1.

<sup>2</sup> A CENSOR Set/Clear cycle is defined as switching the bits from 1 to 0 to 1.

<sup>3</sup> Maximum total time @ 150 °C junction temperature ≤ 1 year.

## G.9 Power-Up/Down Sequencing

The supply symbols used in this section are described in [Table G-9](#).

**Table G-9. Power Supply Pin Groups**

| Symbol                                                                 | Types of Power Pins                                                        |
|------------------------------------------------------------------------|----------------------------------------------------------------------------|
| V <sub>DDH</sub><br>(High Voltage Supply Group)                        | Supply to the 5-V pads for output driver (V <sub>DDH</sub> )               |
|                                                                        | Supply to the analog (QADC64E) circuitry (V <sub>DDA</sub> )               |
|                                                                        | High voltage supply to the Flash module (V <sub>FLASH</sub> ) <sup>1</sup> |
| V <sub>DDL</sub><br>(Low Voltage Supply Pins)                          | Supply to low voltage pad drivers (QVDDL, NVDDL)                           |
|                                                                        | Supply to all low voltage internal logic (V <sub>DD</sub> )                |
|                                                                        | Supply to low voltage Flash circuitry (V <sub>DDF</sub> ) <sup>1</sup>     |
|                                                                        | Supply to system PLL                                                       |
| V <sub>DDKA</sub><br>(Low Voltage Keep-Alive Supply Pins) <sup>2</sup> | Supply to IRAMSTBY                                                         |
|                                                                        | Supply to oscillator and other circuitry for keep-alive functions (KAPWR). |

<sup>1</sup> These power supplies are only available on the MPC563 and MPC564.

<sup>2</sup> Any supply in the V<sub>DDKA</sub> group can be powered with the V<sub>DDL</sub> if the function which it supplies is not required during "Keep-alive."

There are two power-up/down options. Choosing which one is required for an application will depend upon circuitry connected to 2.6-V compliant pins and dual 2.6-V/5-V compliant pins. Power-up/down option A is required if 2.6-V compliant pins and dual 2.6-V/5-V compliant pins are connected to the 5-V supply with a pull-up resistor or driven by 5-V logic during power-up/down. In applications for which this scenario is not true the power-up/down option B may be implemented. Option B is less stringent and easier to ensure over a variety of applications.

Refer to [Table 2-1](#) for a list of 2.6 V and dual 2.6V/5 V compliant pins.

The power consumption during power-up/down sequencing will stay below the operating power consumption specifications when following these guidelines.

#### NOTE:

The  $V_{DDH}$  ramp voltage should be kept below 50V/ms and the  $V_{DDL}$  ramp rate less than 25V/ms.

### G.9.1 Power-Up/Down Option A

The Option A power-up sequence (excluding  $V_{DDKA}$ ) is

1.  $V_{DDH} \leq V_{DDL} + 3.1 \text{ V}$  ( $V_{DDH}$  cannot lead  $V_{DDL}$  by more than 3.1 V)
2.  $V_{DDH} \geq V_{DDL} - 0.5 \text{ V}$  ( $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V)

The first step in the sequence is required is due to gate-to-drain stress limits for transistors in the pads of 2.6-V compliant pins and dual 2.6-V/5-V compliant pins. Damage can occur if gate-to-drain voltage potential is greater than 3.1 V. This is only a concern at power-up/down. The second step in the sequence is required is due to ESD diodes in the pad logic for dual 2.6-V/5-V compliant pins and 2.6-V pins. The diodes are forward biased when  $V_{DDL}$  is greater than  $V_{DDH}$  and will start to conduct current.

[Figure G-1](#) illustrates the power-up sequence if no keep-alive supply is required. [Figure G-2](#) illustrates the power-up sequence if a keep-alive supply is required. The keep-alive supply should be powered-up at the same instant or before both the high voltage and low voltage supplies are powered-up.

**Figure G-1. Option A Power-Up Sequence Without Keep-Alive Supply**

**Figure G-2. Option A Power-Up Sequence With Keep-Alive Supply**

The option A power-down sequence (excluding  $V_{DDKA}$ ) is

1.  $V_{DDH} \leq V_{DDL} + 3.1 \text{ V}$  ( $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 3.1 V)
2.  $V_{DDH} \geq V_{DDL} - 0.5 \text{ V}$  ( $V_{DDH}$  cannot lead  $V_{DDL}$  by more than 0.5 V)

Figure G-3 illustrates the power-down sequence if no keep-alive supply is required.

**Figure G-3. Option A Power-Down Sequence Without Keep-Alive Supply**

Figure G-4 illustrates the power-down sequence if a keep-alive supply is required.

**Figure G-4. Option A Power-Down Sequence With Keep-Alive Supply**

## G.9.2 Power-Up/Down Option B

A less stringent power-up sequence may be implemented if 2.6-V compliant pins and dual 2.6-V/5-V compliant pins are NOT connected to the 5-V supply with a pull-up resistor or driven by 5-V logic during power-up/down.

The option B power-up sequence (excluding  $V_{DDKA}$ ) is:

1.  $V_{DDH} > V_{DDL} - 0.5 \text{ V}$  ( $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V)

Thus the  $V_{DDH}$  supply group can be fully powered-up prior to power-up of the  $V_{DDL}$  supply group, with no adverse affects to the device.

The requirement that  $V_{DDH}$  cannot lag  $V_{DDL}$  by more than 0.5 V is due to ESD diodes in the pad logic for dual 2.6-V/5-V compliant pins and 2.6-V pins. The diodes are forward biased when  $V_{DDL}$  is greater than  $V_{DDH}$  and will start to conduct current.

Figure G-5 illustrates the power-up sequence if no keep-alive supply is required. Figure G-6 illustrates the power-up sequence if a keep-alive supply is required. The keep-alive supply should be powered-up at the same time or before both the high voltage and low voltage supplies are powered-up.

**Figure G-5. Option B Power-Up Sequence Without Keep-Alive Supply**

**Figure G-6. Option B Power-Up Sequence With Keep-Alive Supply**

The option B power-down sequence (excluding  $V_{DDKA}$ ) is:

1. The  $V_{DDL}$  supply group can be fully powered-down prior to power-down of the  $V_{DDH}$  supply group, with no adverse affects to the device.

For power-down, the low voltage supply should come down before the high voltage supply, although with varying loads, the high voltage may actually get ahead.

[Figure G-7](#) illustrates the power-down sequence if no keep-alive supply is required. [Figure G-8](#) illustrates the power-down sequence if a keep-alive supply is required.

**Figure G-7. Option B Power-Down Sequence Without Keep-Alive Supply**

**Figure G-8. Option B Power-Down Sequence with Keep-Alive Supply**

## G.10 Issues Regarding Power Sequence

### G.10.1 Application of $\overline{\text{PORESET}}$ or $\overline{\text{HRESET}}$

When  $V_{DDH}$  is rising and  $V_{DDL}$  is at 0.0 V, as  $V_{DDH}$  reaches 1.6 V, all 5 V drivers are tristated. Before  $V_{DDH}$  reaches 1.6V, all 5 V outputs are unknown. If  $V_{DDL}$  is rising and  $V_{DDH}$  is at least 3.1V greater than  $V_{DDL}$ , then the 5 V drivers can come out of tristate when  $V_{DDL}$  reaches 1.1V, and the 2.6 V drivers can start driving when  $V_{DDL}$  reaches 0.5 V. For these reasons, the  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  signal must be asserted during power-up before  $V_{DDL}$  is above 0.5 V.

If the  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  signal is not asserted before this condition, there is a possibility of disturbing the programmed state of the flash. In addition, the state of the pads are indeterminant until  $\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  propagates through the device to initialize all circuitry.

## G.10.2 Keep-Alive RAM

$\overline{\text{PORESET}}$  or  $\overline{\text{HRESET}}$  must be asserted during power-down prior to any supply dropping out of specified operating conditions.

An additional constraint is placed on  $\overline{\text{PORESET}}$  assertion since it is an asynchronous input. To assure that the assertion of  $\overline{\text{PORESET}}$  does not potentially cause stores to keep-alive RAM to be corrupted (store single or store multiple) or non-coherent (store multiple), either of the following solutions is recommended:

- Assert  $\overline{\text{HRESET}}$  at least 0.5  $\mu\text{s}$  prior to when  $\overline{\text{PORESET}}$  is asserted.
- Assert  $\overline{\text{IRQ0}}$  (non-maskable interrupt) at least 0.5  $\mu\text{s}$  prior to when  $\overline{\text{PORESET}}$  is asserted. The service routine for  $\overline{\text{IRQ0}}$  should not perform any writes to keep-alive RAM.

The amount of delay that should be added to  $\overline{\text{PORESET}}$  assertion is dependent upon the frequency of operation and the maximum number of store multiples executed that are required to be coherent. If store multiples of more than 28 registers are needed and if the frequency of operation is lower than 66 MHz, the delay added to  $\overline{\text{PORESET}}$  assertion will need to be greater than 0.5  $\mu\text{s}$ . In addition, if KAPWR features are being used,  $\overline{\text{PORESET}}$  should not be driven low while the  $V_{\text{DDH}}$  and  $V_{\text{DDL}}$  supplies are off.

## G.11 AC Timing

Figure G-9 displays generic examples of MPC561/MPC563 timing. Specific timing diagrams are shown in Figure G-10 through Figure G-35.

Figure G-9. Generic Timing Examples

**Table G-10. Bus Operation Timing**

**Note:** ( $V_{DD} = 2.6 \text{ V} \pm 0.1 \text{ V}$ ,  $V_{DDH} = 5.0 \text{ V} \pm 0.25 \text{ V}$ ,  $T_A = T_L$  to  $T_H$ , 50 pF load unless noted otherwise)

| 30  | CLKOUT Rising Edge to $\overline{TS}$ Valid (Hold Time).                                                                                                                                                                                                                     | 3.6    | —   | ns   |

<sup>1</sup> The timing for  $\overline{BR}$  output is relevant when the device MPC561/MPC563 is selected to work with external bus arbiter. The timing for  $\overline{BG}$  output is relevant when the MPC561/MPC563 is selected to work with internal bus arbiter.

<sup>2</sup> The setup times required for  $\overline{TA}$ ,  $\overline{TEA}$ , and  $\overline{BI}$  are relevant only when they are supplied by the external device (and not the memory controller).

<sup>3</sup> The maximum value of spec 8 for DATA[0:31] pins must be extended by 1.1 ns if the pins have been precharged to greater than  $V_{DDL}$ . This is the case if an external slave device on the bus is running at the max. value of  $V_{DATAPC}$ . This is currently specified at 3.1 V. The 1.1 ns addition to spec 8 reflects the expected timing degradation for 3.1 V.

<sup>4</sup> The device may be used without limitation in conjunction with 2.6 V external memories. Pre-discharge function is not available for 66-MHz operation.

<sup>5</sup> The timing 27 refers to  $\overline{CS}$  when  $ACS = '00'$  and to  $\overline{WE}[0:3]/\overline{BE}[0:3]$  when  $CSNT = '0'$ .

## NOTE

The D[0:31] input timings 17 and 18 refer to the rising edge of the CLKOUT in which the  $\overline{TA}$  input signal is asserted.

**Figure G-29. Auxiliary Port Data Input Timing Diagram**

**Figure G-30. Auxiliary Port Data Output Timing Diagram**

MDO and  $\overline{\text{MSEO}}$  data is held valid until the next MCKO low transition.

When  $\overline{\text{RSTI}}$  is asserted,  $\overline{\text{EVTI}}$  is used to enable or disable the auxiliary port. Because MCKO probably is not active at this point, the timing must be based on the system clock. Since the system clock is not realized on the connector, its value must be known by the tool.

| 53  | DSDI, DSCK set up                                                                                              | 46     | —   | ns   |
| 54  | DSDI, DSCK hold time                                                                                           | 0      | —   | ns   |
| 55  | $\overline{\text{SRESET}}$ negated to CLKOUT rising edge for DSDI and DSCK sample                              | 121    | —   | ns   |
| 55a | $\overline{\text{HRESET}}$ , $\overline{\text{SRESET}}$ , $\overline{\text{PORESET}}$ pulse width <sup>2</sup> | 100    | —   | ns   |

- <sup>1</sup> Weak pull-ups and pull-downs used for Reset timing will comply with the 130  $\mu$ A mode select current outlined in [Table G.6](#) on page G-7. The system requires two clocks of hold time on  $\overline{\text{RSTCONF/TEXP}}$  after negation of  $\overline{\text{HRESET}}$ . The simplest way to insure meeting this requirement in systems that require the use of the TEXP function, is to connect  $\overline{\text{RSTCONF/TEXP}}$  to  $\overline{\text{SRESET}}$ .
- <sup>2</sup>  $\overline{\text{HRESET}}$ ,  $\overline{\text{SRESET}}$  and  $\overline{\text{PORESET}}$  have a glitch detector to ensure that spikes less than 20 ns are rejected. The internal  $\overline{\text{HRESET}}$ ,  $\overline{\text{SRESET}}$  and  $\overline{\text{PORESET}}$  will assert only if these signals are asserted for more than 100 ns.

<sup>1</sup> Conversion characteristics vary with  $F_{QCLK}$  rate. Reduced conversion accuracy occurs at max  $F_{QCLK}$  rate.

<sup>2</sup> The number of conversion cycles is dependent on the IST bit in the CCW register.

<sup>3</sup> At  $V_{RH} - V_{RL} = 5.12 \text{ V}$ , one count = 5 mV.

<sup>4</sup> Accuracy tested and guaranteed at  $V_{RH} - V_{RL} = 5.0 \text{ V} \pm 0.25 \text{ V}$

<sup>5</sup> This parameter is periodically sampled rather than 100% tested.

<sup>6</sup> Absolute error includes 1/2 count (~2.5 mV) of inherent quantization error and circuit (differential, integral, and offset) error. Specification assumes that adequate low-pass filtering is present on analog input pins — capacitive filter with 0.01  $\mu\text{F}$  to 0.1  $\mu\text{F}$  capacitor between analog input and analog ground, typical source isolation impedance of 10  $\text{K}\Omega$ .

<sup>7</sup> Input signals with large slew rates or high frequency noise components cannot be converted accurately. These signals may affect the conversion accuracy of other channels.

- <sup>8</sup> Accuracy tested and guaranteed at  $V_{ARH} - V_{RL} = 1.0V$  to  $0.75 \times V_{DDA}$  V. See Specification 52 in <XrefBlue>Table G-4 on page G-7.
- <sup>9</sup> This parameter is periodically sampled rather than 100% tested.
- <sup>10</sup> Absolute error includes 1/2 count (~2.5 mV) of inherent quantization error and circuit (differential, integral, and offset) error. Specification assumes that adequate low-pass filtering is present on analog input pins — capacitive filter with 0.01  $\mu F$  to 0.1  $\mu F$  capacitor between analog input and analog ground, typical source isolation impedance of 10 K $\Omega$ .
- <sup>11</sup> Input signals with large slew rates or high frequency noise components cannot be converted accurately. These signals may affect the conversion accuracy of other channels.
- <sup>12</sup> Below disruptive current conditions, the channel being stressed has conversion values of 0x3FF for analog inputs greater than  $V_{RH}$  and 0x000 for values less than  $V_{RL}$ . This assumes that  $V_{RH} \leq V_{DDA}$  and  $V_{RL} \geq V_{SSA}$  due to the presence of the sample amplifier. Other channels are not affected by non-disruptive conditions.
- <sup>13</sup> Exceeding limit may cause conversion error on stressed channels and on unstressed channels. Transitions within the limit do not affect device reliability or cause permanent damage.
- <sup>14</sup> Input must be current limited to the value specified. To determine the value of the required current-limiting resistor, calculate resistance values using  $V_{POSCLAMP} = (\text{the lower of } V_{DDA} \text{ or } V_{DDH}) + 0.3 \text{ V}$  and  $V_{NEGCLAMP} = -0.3 \text{ V}$ , then use the larger of the calculated values. The diode drop voltage is a function of current and varies approximately 0.4 to 0.8 V over temperature
- <sup>15</sup> This parameter is periodically sampled rather 100% tested.
- <sup>16</sup> Derate linearly to 0.3 mA if  $V_{DDH} - V_{DDA} = 1 \text{ V}$ . This specification is preliminary and may change after further characterization.
- <sup>17</sup> Condition applies to two adjacent pins.
- <sup>18</sup> Condition applies to all analog channels.
- <sup>19</sup> Note that -ve means current flows out of the pin.
- <sup>20</sup> Current Coupling Ratio, K, is defined as the ratio of the output current,  $I_{OUT}$ , measured on the pin under test to the injection current,  $I_{INJ}$ , when both adjacent pins are overstressed with the specified injection current.  $K = I_{OUT} / I_{INJ}$  The input voltage error on the channel under test is calculated as  $V_{err} = I_{INJ} \times K \times R_S$ .
- <sup>21</sup> Maximum source impedance is application-dependent. Error resulting from pin leakage depends on junction leakage into the pin and on leakage due to charge-sharing with internal capacitance. Error from junction leakage is a function of external source impedance and input leakage current. In the following expression, expected error in result value due to junction leakage is expressed in voltage ( $V_{ERRJ}$ ):  $V_{ERRJ} = R_S \times I_{OFF}$  where  $I_{OFF}$  is a function of operating temperature. Charge-sharing leakage is a function of input source impedance, conversion rate, change in voltage between successive conversions, and the size of the filtering capacitor used. Error levels are best determined empirically. In general, continuous conversion of the same channel may not be compatible with high source impedance
- <sup>22</sup> For a maximum sampling error of the input voltage  $\leq 1\text{LSB}$ , then the external filter capacitor,  $C_f \geq 1024 \times C_{SAMP}$  The value of  $C_{SAMP}$  in the new design may be reduced.

<sup>1</sup> All AC timing is tested to the 5-V levels outlined in <XrefBlue>Table G.6 on page G-7

<sup>2</sup> TC is defined to be the clock period.

<sup>3</sup> For high time, n = External SCK rise time; for low time, n = External SCK fall time.

**Table G-18. QSCI Timing**

**Note:** ( $T_A = T_L$  to  $T_H$ , 50 pF load on all SCI pins unless otherwise noted)

**Note:** All AC timing is tested to the 5-V levels outlined in [Table G.6](#)

|         | Serial Pins (Maximum frequency)                                                                                              | $t_F$       | 1   | —               | MHz            |

<sup>1</sup> AC timing is shown is tested to the 3-V levels outlined in <XrefBlue>Table G-4 on page G-7.

## G.20 PPM Timing Characteristics

Table G-22. PPM Timing

Note: ( $T_A = T_L$  to  $T_H$ , 50 pF Load on all Pins)

| Nu<br>m | Rating                                | Symbol    | Min                               | Max              | Unit |
|---------|---------------------------------------|-----------|-----------------------------------|------------------|------|
| 131     | Operating Frequency <sup>1</sup>      | $f_{OP}$  | $f_{SYS}/256$                     | $f_{SYS}/2^2$    | Hz   |
| 132     | Cycle Time                            | $t_{CYC}$ | $2 \cdot TC$                      | $256 \cdot TC^3$ | ns   |
| 133     | PPM Clock (PPM_TCLK) high or low time | $t_{SW}$  | $(t_{cyc}/2) - (t_{RO} + t_{FI})$ |                  | ns   |
| 134     | Sequential Transfer Delay             | $t_{TD}$  | $9 \cdot tcyc$                    | $17 \cdot tcyc$  | ns   |
| 135     | Data Setup Time (Inputs)              | $t_{SU}$  | 30                                | —                | ns   |
| 136     | Data Hold Time (Inputs)               | $t_{HI}$  | 0                                 | —                | ns   |
| 137     | Data Valid (After PPM_TCLK Edge)      | $t_V$     | —                                 | 5                | ns   |
| 138     | Data Hold Time (Outputs)              | $t_{HO}$  | $TC/2$                            | —                | ns   |

**Table G-22. PPM Timing (continued)**

**Note:** ( $T_A = T_L$  to  $T_H$ , 50 pF Load on all Pins)

| Num | Rating                                                                         | Symbol   | Min    | Max     | Unit     |
|-----|--------------------------------------------------------------------------------|----------|--------|---------|----------|
| 139 | Rise Time                                                                      | $t_{HI}$ | —      | 1       | $\mu s$  |
|     | Input                                                                          |          |        |         |          |
|     | Output –<br>2.6V PPM pads (PDMCR2[PPMV] = 0)<br>5V PPM pads (PDMCR2[PPMV] = 1) | $t_{RO}$ | —<br>— | 7<br>15 | ns<br>ns |
| 140 | Fall Time                                                                      | $t_{FI}$ | —      | 1       | $\mu s$  |
|     | Input                                                                          |          |        |         |          |
|     | Output –<br>2.6V PPM pads (PDMCR2[PPMV] = 0)<br>5V PPM pads (PDMCR2[PPMV] = 1) | $t_{FO}$ | —<br>— | 7<br>15 | ns<br>ns |

<sup>1</sup> All AC timing is tested to the 2.6-V levels outlined in <XrefBlue>Table G.6 on page G-7.

<sup>2</sup> Although the PPM permits frequencies of up to  $f_{SYS}/2$ , if the 5-V bus is selected the bus frequency should not be run at frequencies above  $f_{SYS}/8$  for EMI/EMC reasons.

<sup>3</sup> TC is defined to be the clock period.

Following are PPM timing diagrams.

**Figure G-44. PPM\_TCLK Timing**

**Figure G-45. PPM Data Transfer Timing (SPI Mode)**

## G.21 MIOS Timing Characteristics

All MIOS output pins are slew rate controlled. Slew rate control circuitry adds 90 ns as minimum to the output timing and 650 ns as a maximum. This slew rate is from 10%  $V_{DD}$  to 90%  $V_{DD}$ , an additional 100 ns should be added for total 0 to  $V_{DD}$  slew rate.

**Table G-23. MCPSM Timing Characteristics**

**Note:** After reset MCPSMSCR\_PSL[3:0] is set to 0b0000.

**Note:** VS\_PCLK is the MIOS prescaler clock which is distributed to all the counter (e.g., MPWMSM and MMCSM) submodules.

| Characteristic                             | Symbol             | Delay                   | Unit                |
|--------------------------------------------|--------------------|-------------------------|---------------------|
| MCPSM enable to VS_PCLK pulse <sup>1</sup> | $t_{\text{CPSMC}}$ | (MCPSMSCR_PSL[3:0]) - 1 | System Clock Cycles |

<sup>1</sup> The MCPSM clock prescaler value (MCPSMSCR\_PSL[3:0]) should be written to the MCPSMSCR (MCPSM Status/Control Register) before rewriting the MCPSMSCR to set the enable bit (MCPSMSCR\_PREN). If this is not done the prescaler will start with the old value in the MCPSMSCR\_PSL[3:0] before reloading the new value into the counter.

Note 1:  $f_{\text{SYS}}$  is the internal system clock for the IMB3 bus.

Note 2: The numbers associated with the  $f_{\text{SYS}}$  ticks refer to the IMB3 internal state.

Note 3: vs\_pclk is the MIOS prescaler clock which is distributed around the MIOS to counter modules such as the MMCSM and MPWMSM.

**Figure G-46. MCPSM Enable to VS\_PCLK Pulse Timing Diagram**

## G.21.1 MPWMSM Timing Characteristics

**Table G-24. MPWMSM Timing Characteristics**

**Note:** All delays are in system clock periods.

| Characteristic                                 | Symbol            | Min                                                                                                                                                            | Max              |
|------------------------------------------------|-------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------|
| PWMSM output resolution                        | $t_{\text{PWMR}}$ | — <sup>1</sup>                                                                                                                                                 | 2.0 <sup>2</sup> |
| PWM output pulse <sup>3</sup>                  | $t_{\text{PWMO}}$ | 2.0                                                                                                                                                            | —                |
| MPWMI input pin to MPWMSCR_PIN status set      | $t_{\text{PIN}}$  | 1                                                                                                                                                              | 2                |
| CPSM enable to output set <sup>4</sup>         | $t_{\text{PWMP}}$ | $(\text{MPWMPERR} - \text{MPWMPULR} + 1) * (256 - \text{MPWMSCR\_CP}) * \text{MCPSMSCR\_PSL} + 1$                                                              |                  |
| MPWMSM Enable to output set (MIN) <sup>5</sup> | $t_{\text{PWME}}$ | $(\text{MPWMPERR} - \text{MPWMPULR}) * (256 - \text{MPWMSCR\_CP}) * \text{MCPSMSCR\_PSL} + 3 + (255 - \text{MPWMSCR\_CP}) * \text{MCPSMSCR\_PSL}$ <sup>6</sup> |                  |

**Table G-24. MPWMSM Timing Characteristics**

**Note:** All delays are in system clock periods.

| Characteristic                                                 | Symbol     | Min                                                       | Max |
|----------------------------------------------------------------|------------|-----------------------------------------------------------|-----|
| MPWMSM Enable to output set (MAX) <sup>5</sup>                 | $t_{PWME}$ | $t_{PWME}(\text{MIN}) + \text{MCPSMSCR\_PSL} - 1^6$       |     |
| Interrupt Flag to output pin reset (period start) <sup>7</sup> | $t_{FLGP}$ | $(256 - \text{MPWMSCR\_CP}) * \text{MCPSMSCR\_PSL} - 1^6$ |     |

<sup>1</sup> Minimum output resolution depends on MPWMSM and MCPSM prescaler settings.

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSL[3:0] = 0x2 and MPWMSCR\_CP[7:0] = 0xFF.

<sup>3</sup> Excluding the case where the output is always "0".

<sup>4</sup> With MPWMSM enabled before enabling the MCPSM. Please also see NOTE 1 on the MCPSM timing information.

<sup>5</sup> The exact timing from MPWMSM enable to the pin being set depends on the timing of the register write and the MCPSM VS\_PCLK.

<sup>6</sup> When MCPSMSCR\_PSL = 0x0000, this gives a prescale value of 16 and it is 16 which should be used in these calculations. When MCPSMSCR\_PSL = 0x0001, the CPSM is inactive.

<sup>7</sup> The interrupt is set before the output pin is reset (Signifying the start of a new period).

**Figure G-47. MPWMSM Minimum Output Pulse Example Timing Diagram**

## G.21.2 MMCSM Timing Characteristics

Table G-25. MMCSM Timing Characteristics

**Note:** All delays are in system clock periods.

| Characteristic                                | Symbol      | Min                                                      | Max            |
|-----------------------------------------------|-------------|----------------------------------------------------------|----------------|
| MMCSM input pin period                        | $t_{PPER}$  | 4                                                        | —              |
| MMCSM pin low time                            | $t_{PLO}$   | 2                                                        | —              |
| MMCSM pin high time                           | $t_{PHI}$   | 2                                                        | —              |
| clock pin to counter bus increment.           | $t_{PCCB}$  | 1                                                        | 2              |
| load pin to new counter bus value             | $t_{PLCB}$  | 1                                                        | 2              |
| clock pin to PINC delay                       | $t_{PINC}$  | 1                                                        | 2              |
| Load pin to PINL delay                        | $t_{PINL}$  | 1                                                        | 2              |
| Counter bus resolution                        | $t_{CBR}$   | — <sup>1</sup>                                           | 2 <sup>2</sup> |
| Counter bus overflow reload to interrupt flag | $t_{CBFLG}$ | 1                                                        |                |
| MCPSM enable to counter bus increment.        | $t_{MCMP}$  | $(256 - \text{MMCSMSCR\_CP}) * \text{MCPSMSCR\_PSL} + 2$ |                |

**Table G-25. MMCSM Timing Characteristics (continued)**

**Note:** All delays are in system clock periods.

| Characteristic                                           | Symbol     | Min                                                                | Max |
|----------------------------------------------------------|------------|--------------------------------------------------------------------|-----|
| MMCSM Enable to counter bus increment (MIN) <sup>3</sup> | $t_{MCME}$ | $4 + MCPSMSCR\_PSL * (255 - MMCSMSCR\_CP)^3$                       |     |
| MMCSM Enable to counter bus increment (MAX) <sup>3</sup> | $t_{MCME}$ | $4 + MCPSMSCR\_PSL * (255 - MMCSMSCR\_CP) + (MCPSMSCR\_PSL - 1)^3$ |     |

<sup>1</sup> Minimum output resolution depends on MMCSM and MCPSM prescaler settings.

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSL[3:0] = 0x2 and MMCSMSCR\_CP[7:0] = 0xFF.

<sup>3</sup> The exact timing from MMCSM enable to the pin being set depends on the timing of the MMCSMSCR register write and the MCPSM VS\_PCLK. The MMCSM enable is taken to mean the MMCSMSCR\_CLS[1:0] being written to 2'b11.

**Figure G-51. MMCSM Minimum Input Pin (Either Load or Clock) Timing Diagram**

### NOTE

$f_{SYS}$  is the internal system clock for the IMB3 bus.

**Figure G-52. MMCSM Clock Pin to Counter Bus Increment Timing Diagram**

Figure G-53. MMCSM Load Pin to Counter Bus Reload Timing Diagram

Figure G-54. MMCSM Counter Bus Reload to Interrupt Flag Setting Timing Diagram

Figure G-55. MMCSM Prescaler Clock Select to Counter Bus Increment Timing Diagram

## G.21.3 MDASM Timing Characteristics

Table G-26. MDASM Timing Characteristics

**Note:** All delays are in system clock periods.

| Characteristics                   | Symbol     | Min | Max |
|-----------------------------------|------------|-----|-----|
| Input Modes: (IPWM, IPM, IC, DIS) |            |     |     |
| MDASM input pin period            | $t_{PPER}$ | 4   | —   |
| MDASM pin low time                | $t_{PLO}$  | 2   | —   |

**Table G-26. MDASM Timing Characteristics (continued)**

**Note:** All delays are in system clock periods.

| Characteristics                        | Symbol      | Min | Max   |
|----------------------------------------|-------------|-----|-------|
| MDASM pin high time                    | $t_{PHI}$   | 2   | —     |
| Input capture resolution               | $t_{CAPR}$  | —   | 2     |
| Input pin to Counter Bus capture delay | $t_{PCAP}$  | 1   | $3^1$ |
| Input pin to interrupt flag delay      | $t_{PFLG}$  | 2   | 3     |
| Input pin to PIN delay                 | $t_{PIN}$   | 1   | 2     |
| Counter bus resolution                 | $t_{CBR}$   | —   | $2^2$ |
| <b>Output Modes: (OC, OPWM)</b>        |             |     |       |
| Output pulse width <sup>3</sup>        | $t_{PULW}$  | 2   | —     |
| Compare resolution <sup>3</sup>        | $t_{COMR}$  | —   | $2^2$ |
| Counter Bus to pin change              | $t_{CBP}$   | 3   |       |
| Counter Bus to interrupt flag set.     | $t_{CBFLG}$ | 3   |       |

<sup>1</sup> If the counter bus capture occurs when the counter bus is changing then the capture is delayed one cycle. In situations where the counter bus is stable when the input capture occurs the  $t_{PCAP}$  has a maximum delay of two cycles (the one-cycle uncertainty is due to the synchronizer).

<sup>2</sup> Maximum resolution is obtained by setting CPSMPSL[3:0] = 0x2 and MDASMSR\_CP[7:0] = 0xFF.

<sup>3</sup> Maximum output resolution and pulse width depends on counter (e.g., MMCSM) and MCPSM prescaler settings.

**Figure G-56. MDASM Minimum Input Pin Timing Diagram**

### NOTE

$f_{SYS}$  is the internal system clock for the IMB3 bus.

Figure G-61. Counter Bus to MDASM Interrupt Flag Setting Timing Diagram

## G.22 MPIO SM Timing Characteristics

Table G-27. MPIO SM Timing Characteristics

**Note:** All delays are in system clock periods.

| Characteristic                  | Symbol     | Min            | Max |
|---------------------------------|------------|----------------|-----|
| <b>Input Mode</b>               |            |                |     |
| MPIO SM input pin period        | $t_{PPER}$ | — <sup>1</sup> | —   |
| MPIO SM pin low time            | $t_{PLO}$  | — <sup>1</sup> | —   |
| MPIO SM pin high time           | $t_{PHI}$  | — <sup>1</sup> | —   |
| Input pin to MPIO SM_DR delay   | $t_{PDR}$  | 0              | 1   |
| <b>Output mode</b>              |            |                |     |
| Output pulse width <sup>2</sup> | $t_{PULW}$ | — <sup>2</sup> | —   |

<sup>1</sup> The minimum input pin period, pin low and pin high times depend on the rate at which the MPIO SM\_DR register is polled.

<sup>2</sup> The minimum output pulse width depends on how quickly the CPU updates the value inside the MPIO SM\_DR register.

Figure G-62. MPIO SM Input Pin to MPIO SM\_DR (Data Register) Timing Diagram

## NOTE

$f_{SYS}$  is the internal system clock for the IMB3 bus.

## G.23 Pin Summary

Table G-28. MPC561/MPC563 Signal Names and Pin Names

| Signal Name       | Pin Name      | Ball Assignment |
|-------------------|---------------|-----------------|
| USIU              |               |                 |
| ADDR/SGPIOA[8:31] | addr_sgpioa8  | AF9             |
|                   | addr_sgpioa9  | AF8             |

**Table G-28. MPC561/MPC563 Signal Names and Pin Names (continued)**

| Signal Name | Pin Name | Ball Assignment |
|-------------|----------|-----------------|
| ALTREF      | altref   | B10             |
| VDDA        | vdda     | D10             |
| VSSA        | vssa     | A9              |
|             |          | B9              |

- <sup>1</sup> This pin also included the MDO5 function on the K27S mask set off the MPC561.  
<sup>2</sup> MPC563 only, no connection on MPC561.

### G.23.1 Package Diagrams

The package for the MPC561/MPC563 is the 388 PBGA (27 x 27 mm, 1.0 mm ball pitch). This package has 352 balls in the perimeter rows and 36 ground balls in the center island for a total of 388 balls. The case outline drawing is 1164-01, as shown in [Figure G-63](#).

**Figure G-63. MPC561/MPC563 Package Footprint (1 of 2)**

## NOTES

1. DIMENSIONS AND TOLERANCING PER ASME Y14.5M-1994.
2. DIMENSIONS IN MILLIMETERS.
3. DIMENSION IS MEASURED AT THE MAXIMUM SOLDER BALL DIAMETER, PARALLEL TO PRIMARY DATUM A.
4. PRIMARY DATUM A AND THE SEATING PLANE ARE DEFINED BY THE SPHERICAL CROWNS OF THE SOLDER BALLS.

| MILLIMETERS |       |       | INCHES                         |     | MILLIMETERS |              |     | INCHES |     |

# Register Index

## A

Associated registers 10-4

## B

BAR (breakpoint address register) 23-53

BBCMCR (BBC module configuration register) 4-19

BR0 - BR3 (emory controller base registers 0 -3) 10-32

Breakpoint counter B value and control register (COUNTB) 23-46

## C

CALRAM\_OTR (CALRAM ownership trace register) 22-17, 22-18

CANCTRL0 (control register 0) 16-27

CANCTRL1 (control register 1) 16-28

CANCTRL2 (control register 2) 16-30

CFSR0 (TPU3 channel function select register 0) 19-16

CFSR1 (TPU3 channel function select register 1) 19-16

CFSR2 (TPU3 channel function select register 2) 19-16

CFSR3 (TPU3 channel function select register 3) 19-16

CIER (TPU3 channel interrupt enable register) 19-15

CISR (TPU3 channel interrupt status register) 19-19

CMPA-CMPD (comparator A-D value registers) 23-41

CMPE-CMPF (comparator E-F value registers) 23-46

CMPG-CMPH (comparator G-H value registers) 23-47

COLIR (change of lock interrupt register) 8-36

COUNTA (breakpoint counter A value and control register) 23-45

COUNTB (breakpoint counter B value and control register) 23-46

CPR0 (TPU3 channel priority register 0) 19-18

CPR1 (TPU3 channel priority register 1) 19-18

CRAM\_RBAX (CALRAM region base address register) 22-15, 22-16

CRAMMCR (CALRAM module configuration register) 22-13

CRAMOV (CALRAM overlay configuration register) 22-17

## D

DDRQA (QADC64E port A data direction registers) 13-14, 14-14

DDRQS (PORTQS data direction register) 15-14

DEC (decrementer register) 6-40

DER (debug enable register) 23-43

DMBR (dual mapping base register) 10-36

DPDR (development port data register) 23-53

DPTRAM

module configuration register (DPTMCR) 20-3

ram base address register (RAMBAR) 20-4

DSCR (TPU3 development support control register) 19-12

DSSR (TPU3 development support status register) 19-14

Dual mapping option register 10-37

## E

ECR (exception cause register) 23-41, 23-42

EIBADR (external interrupt relocation table base address register) 4-25

EMCR (external master control register) 6-29

## G

General-Purpose I/O registers 6-46

GPDI (general-purpose data in register) 18-19

GPDO (general-purpose data out register) 18-18

## H

HSQR0 (TPU3 host sequence register 0) 19-17

HSQR1 (TPU3 host sequence register 1) 19-17

HSSR0 (TPU3 host service request register 0) 19-17

HSSR1 (TPU3 host service request register 1) 19-17

## I

ICTRL (I-bus support control register) 23-51, A-16

IMASK (interrupt mask register) 16-35

Internal memory map register 6-28

## K

Keep alive power registers lock mechanism 8-25

## L

L2U

global region attribute register (L2U\_GRA) 11-16

module configuration register (L2U\_MCR) 11-13

region attribute registers (L2U\_RAX) 11-15

region base address registers (L2U\_RBAX) 11-14

L2U\_GRA (L2U global region attribute register) 11-16

L2U\_MCR (L2U module configuration register) 11-14

L2U\_RAX (L2U region X attribute register) 11-15

L2U\_RBAX (L2U region x base address register) 11-14

LCTRL1 (L-bus support control register 1) 23-47

LCTRL1 (L-bus support control register 2) 23-48

LCTRL2 (L-bus support control register 2) 23-48

## M

MBISM

interrupt registers 17-69

MCPSMCR (MCPSM status/control register) 17-18

MDASMSCR (MDASM status/control register) 17-43

MI\_GRA (global regionattribute register) 4-23

MI\_RA 1 - 3 (region base address registers (1 - 3)) 4-22  
 MI\_RBA 0 - 3 (region base address registers (0 - 3)) 4-21  
 MIOS  
     bus interface (MBISM) Registers 17-13  
 MIOS1  
     interrupt level register 0 (MIOSLVL0) (MIOS1LVL0) 17-69  
     interrupt level register 1 (MIOSLVL1) (MIOS1LVL0) 17-70  
     module and version number register (MIOS1VNR) 17-14  
 MIOS14ER0 interrupt enable register 17-66  
 MIOS14ER1 interrupt enable register 17-68  
 MIOS14MCR (MIOS14 module configuration register) 17-15  
 MIOS14RPR0 request pending register 17-66  
 MIOS14RPR1 request pending register 17-68  
 MIOS14SR0 (interrupt status register) 17-66  
 MIOS14SR0 interrupt status register 17-65, 24-8  
 MIOS14SR1 (interrupt status register) 17-67, 17-68  
 MIOS14SR1 interrupt status register 17-67  
 MIOS14TPCR (test and pin control register) 17-13, 17-14  
 MIOS1LVL0 (MIOS1 interrupt level register 0) 17-69  
 MIOS1LVL1 (MIOS1 interrupt level 1 register) 17-70  
 MISCNT (MISC counter) 20-6, 21-5, 21-9  
 MISRH (multiple input signature register high) 20-5  
 MISRL (multiple input signature register low) 20-6  
 MMCSMCNT (MMCSM up-counter register) 17-23  
 MMCSMML (MMCSM modulus latch register) 17-24  
 MMCSMSCR (MMCSM status/control register) 17-24  
 MPIO SMDDR (MPIO SM data direction register) 17-63  
 MPIO SMDR (MPIO SM data register) 17-62  
 MPWMCNTR (MPWMSM counter register) 17-58  
 MPWMPERR (MPWMSM period register) 17-57  
 MPWMPULR (MPWMSM pulse width register) 17-57  
 MPWMSCR (MPWMSM status/control register) 17-58  
 MSTAT (memory controller status registers) 10-32  
**O**  
 OR0 - OR3 (memory controller option registers 0-3) 10-34  
**P**  
 PDMCR (pads module configuration register) 2-22  
 PDMCR2 (pads module configuration register) 2-23  
 PISCR (periodic interrupt status and control register) 6-44  
 PITC (periodic interrupt timer count register) 6-45  
 PTR (periodic interrupt timer register) 6-45  
 PLPRCR (PLL, low-power, and reset-control register) 8-33  
 Port data direction registers 13-14, 14-13  
 Port data registers 13-13, 14-12  
 PORTQS (port QS data register) 15-12

PPMCCR (module configuration register) 18-10  
 PPMPCR (PPM control register) 18-12  
 PQSPAR (PORTQS pin assignment register) 15-13  
 PRES DIV (prescaler divide register) 16-29  
**Q**  
 QACR0 (QADC64E control register 0) 13-14, 14-14  
 QACR1 (QADC64E control register 1) 13-15, 13-16, 14-16  
 QACR2 (QADC64E control register 2) 13-17, 14-18  
 QADCINT (QADC64E interrupt register) 13-12, 14-11  
 QADCMCR (module configuration register) 13-8, 14-8  
 QASR (status register 0) 14-22  
 QASR (status registers) 13-20  
 QSCI1CR (QSCI1 control register) 15-60  
 QSCI1SR (QSCI1 status register) 15-61  
 QSMCM  
     configuration register (QMCMMCR) 15-8  
     interrupt level registers (QDSCI\_IL, QSPI\_IL) 15-9  
     port QS data register (PORTQS) 15-11  
     PORTQS data direction register (DDRQS) 15-13  
     PORTQS pin assignment register (PQSPAR) 15-12  
     QSCI1 control register (QSCI1CR) 15-60  
     QSCI1 status register (QSCI1SR) 15-61  
     QSPI command RAM (CRx) 15-23  
     QSPI control register 0 (SPCR0) 15-17  
     QSPI control register 1 (SPCR1) 15-19  
     QSPI control register 2 (SPCR2) 15-20  
     QSPI control register 3 (SPCR3) 15-20  
     QSPI registers 15-16  
     QSPI status register (SPSR) 15-21  
     queued SCI1 status and control registers 15-59  
     SCI control register 0 (SCCxR0) 15-46  
     SCI control register 1 (SCCxR1) 15-47  
     SCI data register (SCxDR) 15-50  
     SCI registers 15-45  
     SCI status register (SCxSR) 15-48  
     test register (QTEST) 15-9  
 QSMCMCR (QSMCM module configuration register) 15-8  
 QSPI\_IL (QSPI interrupt level register) 15-10  
**R**  
 RCPU  
     additional implementation-specific registers 3-27  
     condition register (CR) 3-16  
     condition register CR0 field definition 3-17  
     condition register CR1 field definition 3-17  
     condition register crn field - compare instruction 3-17  
     count register (CTR) 3-19  
     dae/source instruction service register (DSISR) 3-22  
     data address register (DAR) 3-23  
     decrementer register (DEC) 3-23  
     EIE, EID, and NRI special-purpose registers 3-25

- floating-point exception cause register (FPECR) 3-26
- floating-point registers (FPRs) 3-12
- floating-point status and control register (FPSCR) 3-13
- general special-purpose registers (SPRG0-SPRG3) 3-24
- general-purpose registers (GPRs) 3-12
- implementation-specific special-purpose registers 3-25

- link register (LR) 3-19
- machine state register (MSR) 3-20
- machine status save/restore register 0 (SRR0) 3-23
- machine status save/restore register 1 (SRR1) 3-23
- OEA register set 3-20
- processor version register (PVR) 3-25
- UISA register set 3-12
- VEA register set - time base 3-20
- READI development control register 24-10, 24-11
- READI device ID register 24-9
- READI DID 24-9
- READI DTA 1 and DTA 2 (READI data trace attributes 1 and 2 registers) 24-17
- READI RWA (READI read/write access register) 24-13
- READI UBA (READI user base access register) 24-12
- READI UDI (READI upload/download information register) 24-15
- Region attribute register (0 - 3) 4-22
- Register diagrams
  - CALRLAM\_OTR (CALRAM ownership trace register) 22-18
  - CANCTRL0 (control register 0) 16-27
  - CANCTRL1 (control register 1) 16-28
  - CANCTRL2 (control register 2) 16-30
  - CFSR0 (TPU3 channel function select register 0) 19-16
  - CFSR1 (TPU3 channel function select register 1) 19-16
  - CFSR2 (TPU3 channel function select register 2) 19-16
  - CFSR3 (TPU3 channel function select register 3) 19-16
  - CIER (TPU3 channel interrupt enable register) 19-15
  - CISR (TPU3 channel interrupt status register) 19-19
  - CMPG-CMPH (comparator G-H value registers) 23-47
  - COUNTA (breakpoint counter A value and control register) 23-45
  - CPR0 (TPU3 channel priority register 0) 19-18
  - CPR1 (TPU3 channel priority register 1) 19-18
  - CRAM\_RBAX (CALRAM region base address register) 22-16
  - CRAMMCR (CALRAM module configuration register) 22-13
  - CRAMOVLC (CALRAM overlay configuration register) 22-17
  - DDRQA (QADC64E port A data direction registers) 13-14, 14-14
  - DDRQS (PORTQS data direction register) 15-14
  - DER (debug enable register) 23-43
  - DSCR (TPU3 development support control register) 19-12
  - DSSR (TPU3 development support status register) 19-14
  - ECR (exception cause register) 23-42
  - EIBADR (external interrupt relocation table base address register) 4-25
  - HSQR0 (TPU3 host sequence register 0) 19-17
  - HSQR1 (TPU3 host sequence register 1) 19-17
  - HSSR0 (TPU3 host service request register 0) 19-17
  - HSSR1 (TPU3 host service request register 1) 19-17
  - IMASK (interrupt mask register) 16-35
  - L2U\_GRA (L2U global region attribute register) 11-16
  - L2U\_MCR (L2U module configuration register) 11-14
  - L2U\_RAX (L2U region X attribute register) 11-15
  - L2U\_RBAX (L2U region x base address register) 11-14
  - LCTRL2 (L-bus support control register 2) 23-48
  - MIOS14SR0 (interrupt status register) 17-66
  - MIOS14SR1 (interrupt status register) 17-67, 17-68
  - MIOS1LVL0 (MIOS1 interrupt level register 0) 17-69
  - MIOS1LVL1 (MIOS1 interrupt level 1 register) 17-70
  - MISCNT (MISC counter) 20-6, 21-5, 21-9
  - MISRH (multiple input signature register high) 20-5
  - MISRL (multiple input signature register low) 20-6

RTC (real-time clock register) 6-43  
 RTCAL (real-time clock alarm register) 6-44  
 RTCSC (real-time clock status and control register) 6-42  
 Rx data register 18-17  
 Rx shifter register 18-18  
 Rx\_config\_1 (Rx configuration register 1) 18-16  
 Rx\_Config\_2 (Rx configuration register 2) 18-16  
 RXECTR (receive error counter) 16-36  
**S**  
 SCALE\_TCLK\_REG (scale tclk register) 18-24  
 SCCR (system clock control register) 8-29  
 SCCxR0 (QSMCM SCI control register 0) 15-46  
 SCCxR1 (QSMCM SCI control register 1) 15-47  
 SCDR (QSMCM SCI data register) 15-51  
 SCxSR (QSMCM SCIx status register) 15-49  
 SGPIO  
     control register (SGPIOCR) 6-48  
     data register 1 (SGPIODT1) 6-46  
     data register 2 (SGPIODT2) 6-47  
 SHORT\_CH\_REG (short channels register) 18-22  
 SHORT\_REG (short register) 18-19  
 SIMASK (SIU interrupt mask register) 6-33  
 SIMASK2 (SIU interrupt mask register 2) 6-34  
 SIMASK3 (SIU interrupt mask register 3) 6-35  
 SIPEND (SIU interrupt pending register) 6-32  
 SIPEND2 (SIU interrupt pending register 2) 6-32  
 SIPEND3 (SIU interrupt pending register 3) 6-33  
 SIU  
     interrupt edge level register (SIEL) 6-35  
     interrupt mask register (SIMASK) 6-33  
     interrupt registers 6-31  
     interrupt vector register (SIVC) 6-35  
 SIU interrupt in-service register 6-37  
 SIUMCR (SIU module configuration register) 6-25  
 SPCR0 (QSPI control register 0) 15-17  
 SPCR1 (QSPI control register 1) 15-19  
 SPCR2 (QSPI control register 2) 15-20  
 SPCR3 (QSPI control register) 15-21  
 SPRG0-SPRG3 (general special-purpose registers 0-3) 3-24  
 SPSR (QSPI status register) 15-21  
 SRR0 (machine status save/restore register 0) 3-23  
 SWSR (software service register) 6-38  
 SYPCR (system protection control register) 6-37  
 System configuration and protection registers 6-24  
 System configuration registers 6-24  
 System protection registers 6-37  
 System timer registers 6-40  
**T**  
 TBREF0 (ime base reference registers) 6-41  
 TBREF1 (time base reference register 1) 6-41  
 TBSCR (time base control and status register) 6-42

TESR (transfer error status register) 6-39  
 TICR (TPU3 interrupt configuration register) 19-14  
 TIMER (free running timer register) 16-31  
 TouCAN  
     CANCTRL0 (control register 0) 16-27  
     CANCTRL1 (control register 1) 16-28  
     CANCTRL2 (control register 2) 16-30  
     CANICR (interrupt configuration register) 16-27  
     CANMCR (module configuration register) 16-25  
     ESTAT (error and status register) 16-33  
     IFLAG (interrupt flag register) 16-36  
     IMASK (interrupt mask register) 16-35  
     PRESDIV (prescaler divide register) 16-29  
     receive buffer 14 mask registers 16-32  
     receive buffer 15 mask registers 16-33  
     receive mask registers 16-7  
     RXGMSKHI (receive global mask registers) 16-31  
     Test configuration register 16-27  
 TPU3  
     channel function select registers (CFSRx) 19-15  
     channel interrupt enable register (CIER) 19-15  
     channel interrupt status register (CISR) 19-19  
     channel priority registers (CPRx) 19-18  
     development support control register (DSCR) 19-12  
     development support status register (DSSR) 19-13  
     host sequence registers (HSQRx) 19-16  
     host service request registers (HSSRx) 19-17  
     interrupt configuration register (TICR) 19-14  
     module configuration register (TPUMCR) 19-11  
     module configuration register 2 (TPUMCR2) 19-19  
     module configuration register 3 (TPUMCR3) 19-21  
     service grant latch register (SGLR) 19-22  
 TPUMCR (TPU3 module configuration register) 19-11  
 TPUMCR2 (TPU3 module configuration register 2) 19-19  
 TPUMCR3 (TPU3 module configuration register 3) 19-21, 19-22  
 Tx data register 18-18  
 Tx\_Config\_1 (Tx configuration register 1) 18-15  
 Tx\_Config\_2 (Tx configuration register 2) 18-15  
**U**  
 UC3FCFIG (hard reset configuration word) 21-16  
 UC3FCTL (UC3F EEPROM high voltage control register) 21-11  
 UIMB  
     module configuration register (UMCR) 12-7  
     pending interrupt request register (UIPEND) 12-8  
     test control register (UTSTCREG) 12-8  
 UIPEND (UIMB pending interrupt request register) 12-9  
 UMC (UIMB module configuration register) 12-7  
**V**  
 VSRMSR (VDDSRM

sensor register) 8-37

**X**

XER (integer exception register) 3-18

# Index

## A

- Accesses
  - clock requirements 13-52, 14-51
- ACKERR 16-34
- Acknowledge error (ACKERR) 16-34
- ADDR[8:31] 9-4, 9-37
- Address
  - mark wakeup 15-59
- address bus 9-37
- Address space 13-11
- address type (AT[0:3]), 9-38
- ALE 23-42
- ALEE 23-44
- Alignment exception 3-49
- ALU-BFU 3-5
- AN 13-7, 14-6
- Analog
  - front-end multiplexer 13-36, 14-37
  - input
    - considerations 13-73, 14-71
    - pins 13-71, 14-70
  - power pins 13-67, 14-66
  - reference pins 13-71, 14-70
  - section contents 13-2, 14-2
  - submodule block diagram 13-34, 14-36
  - supply
    - filtering and grounding 13-69, 14-67
    - pins 13-67, 14-66
  - to digital converter operation 13-34, 14-36
- arbitration, 9-32
- AT[0:3] 9-4
- atomic 9-32
- atomic operation
  - reservation of data 11-7
- atomic update primitives, 3-43

## B

- BAR 3-60, 23-53
- Base ID mask bits 16-32, 16-33
- Baud
  - clock 15-52
- BB 9-7
- BBCMCR 4-19
- BDIP, 9-5
- BE bit 3-21

- Beginning of queue 2 (BQ2) 13-19, 14-20
- BG 9-7
- BI 9-7, 9-40
- Binary
  - divider 13-47, 14-48
  - weighted capacitors 13-36, 14-37
- Bit stuff error (STUFFERR) 16-34
- BITERR 16-34
- BITS 15-18
- Bits per transfer
  - enable (BITSE) 15-24
  - field (BITS) 15-18
- BITSE 15-24, 15-39
- Bit-time 15-51
- BIU 13-2, 13-51, 14-2, 14-51
- BIUSM
  - BIUTEST — BIUSM test configuration register 17-13
  - selecting the time base bus 17-13
- BKPT (TPU asserted) 19-14
- BLC 19-12
- block diagram
  - CALRAM 22-2
  - DPTRAM 20-2
  - JTAG test logic 25-3
  - L2U 11-2
  - memory controller 10-2
  - MIOS 17-1
  - MPC561/MPC563 1-2
  - READI 24-3
  - READI signal interface 24-22
  - TouCAN 16-1
  - UC3F EEPROM 21-1
  - UIMB 12-2
  - USIU 6-3
- block diagrams
  - analog subsystem 13-34
  - BBC module 4-2
  - clock 8-2
  - DECRAM interfaces 4-13
  - MPC561/MPC563 signals 2-2
  - RCPU 3-1
  - USIU 5-2
- BOFFINT 16-35
- Boundary conditions 13-40, 14-41
- boundary scan register 25-4

- BPU 3-4, 3-5
- BQ2 13-19, 13-40, 14-20, 14-41
- BR 9-7
- Branch
  - prediction 3-5
  - processing unit 3-5
  - trace enable 3-21
- Branch latch control (BLC) 19-12
- Branch processing unit 3-4
- branch target buffer 4-14
- Break frame 15-52
- Breakpoint
  - asserted flag (BKPT) 19-14
  - flag (PCBK) 19-14
- Breakpoint counter A value and control register 23-45
- Breakpoint counter B value and control register 23-46
- breakpoints 23-9
- BRKNOMSK 23-50
- BRx registers 10-32
- BTB 4-14
- BURST 9-4, 9-37
- burst indicator (BURST), 9-37
- burst inhibit (BI), 9-40
- burst read cycle (illustration), 9-21
- burst transfer, 9-17
- burst write cycle (illustration), 9-26
- Bus
  - monitor 6-17
  - off interrupt
    - (BOFFINT) 16-35
- bus busy (BB), 9-34
- bus exception control cycles, 9-45
- bus grant (BG), 9-33
- bus interface
  - bus control signals, 9-2
  - bus operation
    - address transfer phase related signals, 9-37
    - arbitration phase, 9-32
    - basic transfer protocol, 9-8
    - burst mechanism, 9-18
    - burst transfer, 9-17
    - bus exception control cycles, 9-45
    - single beat transfer
      - single beat read flow, 9-9
      - single beat write flow, 9-9, 9-11
    - single beat transfer, 9-9
    - storage reservation, 9-42
    - termination signals, 9-40
- bus operations, 9-8
- bus transfer signals, 9-1
- features, 9-1
- signal descriptions, 9-3

- Bus interface unit (BIU) 13-2, 14-2
  - components 13-51, 14-51
- bus request (BR), 9-33
- bus signals (illustration), 9-3
- BUSY 16-16
  - receive message buffer code 16-5
- BYP 13-30, 13-35, 14-31
- Bypass mode 13-35
- BYTES field 3-19

## C

- CA bit 3-19
- cache control instructions, 3-43
- CALRAM
  - CLPS 22-8, 22-9, 22-10
  - operation modes 22-4
  - privileges 22-5
- CAN2.0B
  - system 16-3
- CANCTRL0 16-27
- CANCTRL1 16-28
- CANCTRL2 16-30
- CANICR 16-27
- Carry 3-19
- CCL 19-13
- CCW 13-2, 13-27, 14-2, 14-28
- copyright states 21-30
- C<sub>F</sub> 13-75, 14-73
- CF1 13-21, 14-22
- CF2 13-22, 14-23
- CFSR 19-15
- CGBMSK 23-48
- CH 19-15, 19-18, 19-19
- CHAN 13-31, 14-32
- CHANNEL 19-16
- Channel
  - assignments
    - multiplexed 13-32
    - nonmultiplexed 13-31
  - conditions latch (CCL) 19-13
  - interrupt
    - enable
      - /disable field (CH) 19-15
      - request level (CIRL) 19-15
      - status (CH) 19-19
  - invalid 13-31
  - number (CHAN) 13-31, 14-32
  - orthogonality 19-4
